

Figure 1 Examples of different types of signals and their spectral content.

deterministic signal contaminated with random noise is analyzed with different bandwidths. Decreasing the bandwidth will lower the rms value of the noise in the spectrum, whereas the rms values of the sine components remain the same (the sine components are assumed to be separated in different filter bands). A random signal with a flat (constant) power spectral density over a wide frequency range is called white noise, as it has the same spectral density at all frequencies.

Transient signals are signals of finite and relatively short duration. They are characterized by a certain amount of “energy” in the same way that continuous signals are characterized by a “power” value. Transient signals have spectral content continuously distributed with frequency, and the natural way to scale the spectra is therefore in terms of energy spectral density (ESD) (U^2s/Hz), where U is the unit of the measured signal. The spectral units of the different types of signals are summarized in Table 1.

Nonstationary continuous signals are signals consisting of one or more of the following:

- Sine components with changing amplitudes and/or changing frequencies

- Random signals with statistical properties changing with time
- Transients appearing with varying intervals and with varying characteristics in time and frequency

2.2 Frequency Analysis – Filter and Detector

The purpose of frequency analysis is to estimate the spectral content of the signals.

A frequency analyzer consists of a set of filters and a detector, as shown in Fig. 2. Prior to analysis, the signal has to be conditioned in terms of level (gain/attenuation), and high- and/or low-pass filtering might be applied as well. In digital analyzers antialiasing filters (low-pass filters) are used in order to prevent aliasing, that is, the erroneous appearance of high frequencies as low frequencies in the subsequent analysis. The concepts and assets of digital processing are covered in Chapter 42 and not discussed further here.

Figure 2 Block diagram of a frequency analyzer. The detector works for all the filters in case of a parallel filter bank.

Table 1 Spectral Scaling and Units for Different Signal Types^a

Signal Type	Spectral Scaling and Unit
Deterministic	rms (U) or MS/Power (U^2)
Random	rmsSD (U/\sqrt{Hz}) or PSD (U^2/Hz)
Transient	ESD (U^2s/Hz)

^a U is the unit of the measured quantity (such as Pa or m/s^2). MS is often referred to as “power.”

The *filter* is the frequency selective part that transmits those frequencies in the signal that are inside the passband of the filter. The *detector* detects the power in the transmitted signals in terms of its MS or rms value. In Fig. 2, only one detector is shown, and this is supposed to work as detector for all the filters in the situation of a parallel filter bank.

The filter in the frequency domain is described by its *frequency response function*. It is a complex function of frequency, having magnitude and phase, and defines the relationship between the input and output in the frequency domain as

$$H(f) = Y(f)/X(f) \quad (1)$$

where $H(f)$ is the frequency response function of the filter and $X(f)$ and $Y(f)$ are the complex spectra (Fourier transforms) of the input signal and the output signal, respectively.

2.2.1 Types of Filters There exist four types of filters: low-pass filters, high-pass filters, bandpass filters, and bandstop (or band rejection) filters, as illustrated in Fig. 3. Figure 3 illustrates the filtering process and shows only the magnitude in the frequency domain. Low-pass, high-pass, and bandstop filters are often used in connection with signal conditioning or in preprocessing for other signal analysis applications.

Bandpass filters are used for frequency analysis and are characterized by a number of parameters. An ideal bandpass filter transmits frequencies in a given frequency band (the passband) and rejects frequencies outside the band. Practical (realizable) real-time filters have a frequency response function, as exemplified in Fig. 4, with a passband characterized by a ripple and a transition band with a finite slope. The frequency response function is complex, and Fig. 4 shows only the magnitude. The corresponding phase relates to the delay in the filter. The filter is characterized by

parameters, such as its *center frequency*, *bandwidth*, *ripple*, and *selectivity*.¹

The passband is bounded by a lower limiting frequency f_1 and an upper limiting frequency f_2 , and the bandwidth of the filter, $B = f_2 - f_1$. Frequency f_0 is the frequency in the “middle” (defined later) of the passband and is called the center frequency.

The definition of the bandwidth is not unique for a practical filter. The two most often traditionally used definitions are the 3-dB bandwidth and the “effective noise bandwidth” (sometimes referred to only as the noise bandwidth).

The *3-dB bandwidth* is the bandwidth where the lower and the upper limiting frequencies, f_1 and f_2 , are defined as the frequencies where only half of the power of the signal is transmitted, that is, the frequencies at which the signal is attenuated by 3 dB and the gain in the passband is assumed to be 1 (0 dB). The 3-dB bandwidth might be the relevant descriptor in the analysis of deterministic signals, that is, signals with content at discrete frequencies.

The *noise bandwidth* of a filter is the bandwidth of a corresponding ideal filter that transmits the same amount of power as the filter when both receive white noise as the input signal. The filters are assumed to have the same gain in the passband, which here is a gain of 1 (0 dB). The noise bandwidth relates to the transmission of broadband random signals and is therefore the bandwidth to be used when rescaling a detected MS (power) spectrum to a PSD spectrum for a random signal.

There exist two basic types of bandpass filters, namely constant bandwidth filters (also called absolute bandwidth filters) and constant percentage bandwidth filters (also called relative bandwidth filters).

Constant bandwidth filters have a bandwidth that is independent of the center frequency. Frequency analysis using constant bandwidth filters gives uniform resolution on a linear frequency scale and is the natural choice in analysis of deterministic signals containing

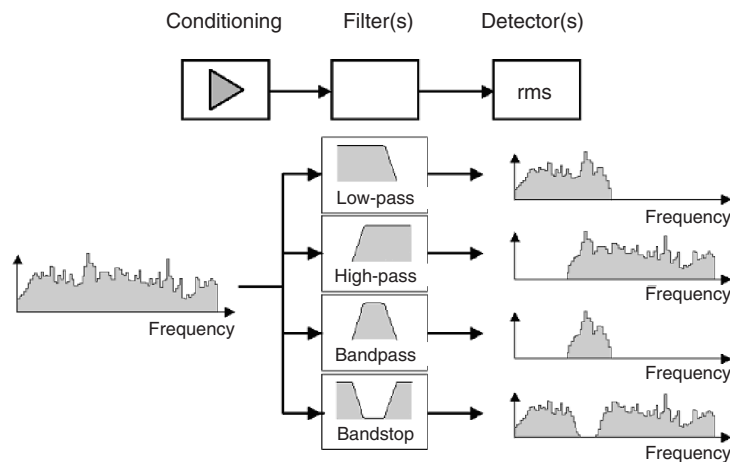

Figure 3 Different types of filters. Low-pass, high-pass, bandpass, and bandstop.

Figure 4 Filter characteristics of an ideal and a practical bandpass filter and definition of noise bandwidth, 3-dB bandwidth, and ripple in the passband.

harmonic components. For constant bandwidth filters the center frequency is defined as the arithmetic mean of f_1 and f_2 , that is, $f_0 = (f_1 + f_2)/2$, which is in the middle between f_1 and f_2 on a linear frequency scale.

Constant percentage bandwidth (CPB) filters have a bandwidth that is a fixed percentage of the center frequency. Octave and fractional-octave filters are examples of constant percentage bandwidth filters often used in acoustics. Octave filters have a bandwidth of approximately 71% and third-octave filters a bandwidth of approximately 23%.

Frequency analysis using constant percentage bandwidth filters gives uniform resolution on a logarithmic frequency scale and is often used when analyzing over a wide frequency range covering three or more decades.

Octave and fractional-octave filters are used extensively in acoustics, as they relate better than constant bandwidth filters do to the human perception of noise.

Other applications are monitoring or quality control measurements facing the following requirements: the bandwidth at low frequencies should be sufficiently narrow to separate the lower harmonic components of rotating elements (containing information about unbalance, misalignment, etc.), and at higher frequencies, the condition of bearings, gears, and the like should be detected in a few filters without the separation of individual components.

For constant percentage bandwidth filters the center frequency is defined as the geometric mean of f_1 and f_2 , that is, $f_0 = \sqrt{f_1 f_2}$, which is in the middle between f_1 and f_2 on a logarithmic frequency scale.

Figure 5 illustrates examples of characteristics of constant bandwidth filters and constant percentage

bandwidth filters. The *selectivity* describes the ability of the filter to separate closely spaced components with large differences in amplitude. For constant bandwidth filters, the bandwidth for 60-dB attenuation or the ratio of this bandwidth to the 3-dB bandwidth, called the shape factor, is used. For constant percentage bandwidth filters, the octave selectivity, which gives the attenuation one octave above and below the center frequency, is used.¹

2.2.2 Filter Response Time and the Uncertainty Principle

So far the characteristics of a filter have been described only by its frequency response function, that is, in the frequency domain. They can be equally well described in the time domain via its *impulse response function*. The time domain and the frequency domain are mathematically related via the Fourier transform, and the impulse response function is the inverse Fourier transform of the frequency response function.

Equation (1) relates the input and the output of a filter in the frequency domain. In the time domain, the output signal $y(t)$ is given by the convolution of the input signal $x(t)$ and the impulse response function $h(t)$ defined by the integral:

$$y(t) = \int_{-\infty}^{\infty} x(\tau)h(t - \tau) d\tau = x(t) * h(t) \quad (2)$$

where the symbol $*$ represents convolution.

A consequence of the impulse response function and the frequency response function being Fourier transform pairs is that if one of them is narrow

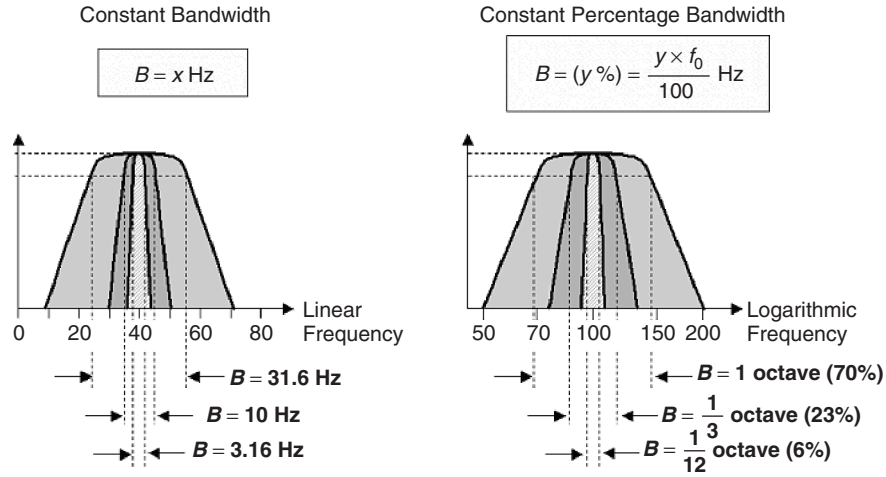

Figure 5 Examples of characteristics of constant bandwidth filters and constant percentage bandwidth filters.

(short), the other one will be wider (longer) than a corresponding minimum width (length). This can be formulated as

$$BT \geq 1 \quad (3)$$

where B is the width in frequency (bandwidth) and T is length in time. The relationship can include various constants depending upon the mathematical definition of B and T , but this is of less importance in this context. This fundamental principle, also known as the *uncertainty principle*, puts a limit to the corresponding resolutions (widths, accuracies) in the two domains and is a consequence of the mathematical formulation of frequency analysis (the Fourier transform). A more loose formulation is: Narrow in one domain means wide in the other domain.

The narrower the frequency response function is (i.e., the higher the resolution in the frequency domain), the longer the impulse response function will be (i.e., the longer it will take for the filter to respond). Figure 6 illustrates the response of a filter when a signal is applied at the input and the relationship between the rise (response) time T_R and the filter bandwidth B . This relationship is just an approximation, and the exact form of the response depends upon the design of the filter. For many practical filters, the time it takes for the filter to settle can be about four to six times the rise time T_R , where $T_R \approx 1/B$.

2.2.3 The Detector To determine the value of the signal after the filtering, a detector is required to estimate the power of the response signal from each of the filters. This is achieved by squaring

Figure 6 Illustration of the response of a filter and the approximate relationship between the rise time T_R and filter bandwidth B .

the response signals (giving instantaneous power) followed by averaging over time giving the mean value of the power or the MS value. Taking the square root of the MS value results in the rms value. Using linear averaging where all the time data within the averaging window are equally weighted, the rms value y_{rms} of a signal $y(t)$ is given by

$$y_{\text{rms}} = \sqrt{\frac{1}{T_A} \int_{T_A} y^2(t) dt} \quad (4)$$

where T_A is the averaging time.

Another common way to average the signal is by using exponential averaging, where the present data is weighted higher than the previous data. This is illustrated in Fig. 7, which shows the detector, its elements, and the linear and exponential averaging functions (weighting on the squared signal).

The weighting for exponential averaging is given by $1/\tau e^{t/\tau}$, $t \leq 0$, where τ is the time constant. When analyzing a random signal, exponential averaging with a time constant τ gives the same statistical accuracy as linear averaging of $T_A = 2\tau$ and 2τ is said to be the equivalent averaging time for exponential averaging. Exponential averaging gives a continuous running average value, whereas linear averaging, in most implementations, is an averaging that stops after the elapsed averaging time.

In acoustics exponential averaging with time constants of 0.125 s (called fast) and 1 s (called slow) are often used. The required averaging time depends upon the type of signal to be analyzed.

For *stationary deterministic signals* averaging over 8 to 10 ripple periods of the squared signal (see Fig. 7)

gives reasonable accuracy. It should be noted that if there is more than one frequency component within the bandwidth, it is the ripple period of the lowest beat frequency that should be considered (the smallest difference in frequency between the components); see Ref. 1.

For *stationary random signals*, the relative standard deviation ε of the estimated rms value is given by

$$\varepsilon = \frac{1}{2\sqrt{BT_A}} \quad (5)$$

or in decibels

$$L_\varepsilon = \frac{4.34}{\sqrt{BT_A}} \text{ dB} \quad (6)$$

where B is the analysis bandwidth and BT_A is assumed $\gg 1$.

As an example, if $BT_A = 100$, then $L_\varepsilon = 0.43$ dB, and there is approximately 68% probability of the level being within ± 0.43 dB around the mean value and approximately 95% probability of the level being within $\pm 2L_\varepsilon = \pm 0.86$ dB around the mean value.

For a *transient signal*, the linear averaging time must be longer than the duration of the filtered transient, that is, longer than the length of the transient plus the length of the longest impulse response function of the filters. A trigger mechanism must be used as well, unless a running linear average with maximum hold is available. Exponential averaging with a time constant (averaging time) much longer (say at least 10 times) than the length of the filtered transient and with maximum hold can also be used. When the time constant is much longer than the filtered signal, the decay of the exponential weighting can be

Figure 7 Schematic illustration of the rms detector and linear and exponential averaging (weighting on the squared signal).

neglected. The detected rms value, however, will be 3 dB too high, as the exponential weighting is twice as high as the linear weighting (with the same averaging time) at time $t = 0$ (see Fig. 7) and this has to be corrected for.

The estimated MS spectrum can be rescaled to PSD (for random signals) by dividing by the analysis noise bandwidth and to ESD (for transient signals) by multiplying the PSD by the averaging time T_A . The averaged (detected) spectrum of a signal $x(t)$ is also referred to as the autospectrum and denoted $G_{XX}(f)$.

For *nonstationary signals*, the averaging time will be a compromise between the ability to follow the changes in the signal and the accuracy in frequency, that is, a compromise between resolution in time and resolution in frequency. This will be discussed later.

Special detectors are used to measure peak values. This is normally done without any filtering, as the peak value is sensitive to filtering.

2.2.4 Stepped, Swept, and Parallel Filter Analysis In a stepped filter analyzer measurement in one filter band at a time is carried out. This is mainly used in analog, compact, low-cost field analyzers or level meters.

Swept filter analysis is performed by scanning a filter through the frequency range of interest. The analysis bandwidth and the averaging time put a limit on how fast the sweep can be performed. Stepped and swept filter analysis require the signal to be stationary, as only one frequency band is analyzed at a time.

Frequency analysis by using a bank of parallel filters and detectors allows for simultaneous analysis of the total signal in all the bands, also referred to as real-time analysis. This method opens the possibility for analysis of nonstationary signals. Most parallel filter analyzer implementations today are digital due to the advances in processing speed and capabilities in digital technology.

3 FREQUENCY ANALYSIS USING FFT

3.1 Discrete Fourier Transform, Weighting and Averaging

Frequency analysis using the fast Fourier transform (FFT) is the most commonly used method for constant bandwidth analysis. The FFT is an algorithm for fast calculation of the discrete Fourier transform (DFT). The DFT is a special form of the Fourier transform working on a block (record) of discrete time samples. The assumption is that the record of time samples represents one period of an artificially periodic time signal having a line (discrete) spectrum, as illustrated in Fig. 8.

Figure 8 Discrete Fourier transform (DFT).

The time signal is sampled with an interval of $\Delta t = 1/f_s$, where f_s is the sampling frequency, and the record contains N samples giving a record length of $T = N\Delta t$. The resulting Fourier spectrum is conjugate even and has $N/2 + 1$ (assuming N is even) complex spectral lines between 0 and $f_s/2$ with a frequency spacing of $\Delta f = 1/T$. Due to the antialiasing filter, not all of the $N/2 + 1$ frequency lines up to $f_s/2$ (called the Nyquist frequency) are valid. In many practical implementations, the relation between the valid frequency span f_{span} and f_s is $f_{span} = f_s/2.56$, which means that a record of N time samples gives a complex spectrum with $N/2.56 + 1$ valid lines. Thus, 2048 time samples gives 801 valid complex frequency lines (including a line at 0 Hz); 4096 time samples gives 1601 valid complex frequency lines, and so forth.

The assumption of the signal as being periodic with a period of T causes no “distortion” in the analysis for sinusoids having an integer number of periods in the record (see Fig. 9a). For other continuous signals not periodic with the record length, the periodic repetition causes distortion at the joints of the periods. This is illustrated in Fig. 9b. The resulting spectrum will be distorted correspondingly. The distortion in the estimated spectrum is also referred to as *leakage* since it appears that power at one frequency leaks out into other frequencies.

To avoid discontinuity at the joints, a smooth weighting function has to be applied on the time record. A very commonly used weighting is the *Hanning weighting*, which is one period of a cosine “lifted” such that it starts and ends at zero amplitude. This is illustrated in Figs. 9c and 9d. When no weighting is used, the weighting is often referred to as *rectangular weighting* or a *uniform weighting*.

For transient signals shorter than the record length, rectangular weighting should be used. For transient

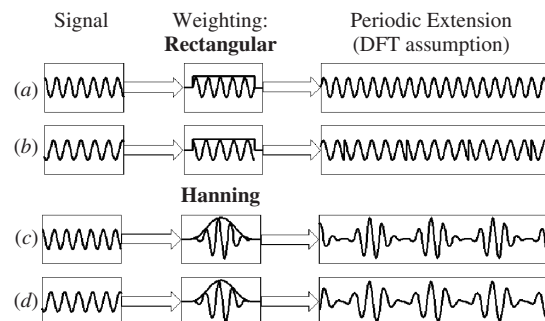

Figure 9 Assumption of periodic repetition in the DFT. An integer number of periods in the record length, (a) and (c). Continuous signal not periodic with the record length, (b) and (d). Rectangular weighting (no weighting) in (a) and (b) and Hanning weighting in (c) and (d). The Hanning weighting minimizes the distortion at the joints for continuous signals that are not periodic with the record length.

signals much shorter than the record length, a rectangular weighting shorter than the record length, with user-defined shift (positioning) and length, can be used. This is often referred to as a *transient weighting* and could in practice include a leading taper and a trailing taper at the edges, making a smooth transition from zero to unity and from unity back to zero inside the record length. The tapers are especially important if the signal contains a dc offset since they will eliminate sharp edges in the weighted signal and thus minimize the distortion in the frequency domain.

The response signal of a lightly damped system when excited by an impact will have a long decay (the system rings for a long time). If the response signal is longer than the record length, an *exponential weighting* can be applied on the signal in order to reduce the effect of the truncation at the end of the record. The exponential weighting is defined by a user-defined shift (perhaps with a leading taper) and a time constant. The extra artificial damping imposed by the exponential weighting can be compensated for subsequently in cases where the measured response signal itself contains exponentially decaying sinusoids (e.g., resonances with viscous damping).

The DFT can also be considered as a filtering process in which each line (frequency) in the spectrum represents the output of a filter centered at that frequency. The weighting function determines the impulse response function of the filter, and the Fourier transform of the weighting function gives the corresponding frequency response function of the filter. Different weighting functions are used in order to optimize the characteristics of the filter. The most common general-purpose weighting function is the

Hanning weighting. This gives a good compromise between bandwidth, ripple in the passband, and selectivity. Of other weighting functions, the *flat-top* and the *Kaiser–Bessel* weighting functions should be mentioned. The flat-top weighting gives a filter with practically no ripple in the passband. It is used in situations in which unbiased estimates of the amplitude of sinusoids is of main interest, such as in the calibration of systems with a sinusoidal input signal. The word *flat* in flat-top refers to the characteristics in the frequency domain. The Kaiser–Bessel weighting is a weighting function that is optimized in terms of selectivity and bandwidth and can be used when closely spaced components with widely different amplitudes have to be separated.^{2,3}

Figure 10 shows the characteristics in the frequency domain of the rectangular, Hanning, Kaiser–Bessel, and flat-top weighting functions, as they are defined in Gade and Herlufsen.² Considering the DFT as a filtering process the spectra (Fourier transforms) of the weighting functions determine the characteristics such as bandwidth, ripple, and selectivity, defined earlier.

Table 2 lists some of the most important filter characteristics for the rectangular, Hanning, flat-top, and Kaiser–Bessel weighting functions as defined in Gade and Herlufsen.² There exist different implementations of the Kaiser–Bessel and the flat-top weighting and the parameters might vary between different implementations. The parameters should therefore only be taken as guidelines for these weighting functions.

The autospectrum, $S_{AA}(f)$, of the signal $a(t)$ is estimated by averaging the squared magnitude of the individual estimates of the complex spectra $A_i(f)$ from each record, which for linear averaging

Figure 10 Rectangular, Hanning, Kaiser–Bessel, and flat-top weighting functions, as they are defined in Ref. 2, in the frequency domain giving the frequency response functions of the filters.

Table 2 Parameters Describing the Filter Characteristics of the Different Weighting Functions as Defined in Ref. 2.^a

Weighting	Rectangular	Hanning	Kaiser–Bessel	Flat Top
Noise bandwidth	$1.0\Delta f$	$1.5\Delta f$	$1.8\Delta f$	$3.8\Delta f$
3-dB bandwidth	$0.9\Delta f$	$1.4\Delta f$	$1.7\Delta f$	$3.7\Delta f$
Ripple	3.9 dB	1.4 dB	1.0 dB	0.01 dB
Highest side lobe	–13 dB	–31 dB	–68 dB	–93 dB
Side-lobe slope per decade	20 dB	60 dB	20 dB	0 dB
60-dB bandwidth	$665\Delta f$	$13.3\Delta f$	$6.1\Delta f$	$9.1\Delta f$

^a There exist different implementations of the Kaiser–Bessel and the flat–top weighting and the parameters might vary between different implementations, and they should therefore only be taken as guidelines for these weighting functions.

is

$$S_{AA}(f) = \frac{1}{N} \sum_{i=1}^N A_i^*(f) A_i(f) \quad (7)$$

where $A_i^*(f)$ is the complex conjugate of $A_i(f)$, that is, $A_i(f)$ with the phase inverted and N is the number of averages. $A_i(f)$ and $S_{AA}(f)$ have content at both positive and negative frequencies (see Fig. 8). The version of the autospectrum that only has content at nonnegative frequencies, that is, where the content at the negative frequencies is “transferred” to the corresponding positive frequencies, is called $G_{AA}(f)$; see Refs. 4 to 6.

The BT_A product used for estimating the relative standard deviation of the estimated rms level in each frequency band, for stationary random signals [see Eqs. (5) and (6)] equals the number of averages of statistically independent records.

3.2 Overlap

Fast Fourier transform works on blocks of data. If the calculation time for a transform is shorter than the record length, it is possible to have overlap between the records (in “real-time” processing).

Applications of overlap analysis:

1. When analyzing random signals, a higher statistical accuracy for a given measurement time can be achieved. The BT_A product used for estimating the relative standard deviation of the estimated rms level depends upon the weighting and the overlap and is given by

$$BT_A = NBT_{\text{eff}} \quad (8)$$

where BT_{eff} is the effective BT product per record for the given weighting and overlap used and N is number of averages. Various BT_{eff} values² are given in Table 3. The numbers for the Kaiser–Bessel and the flat-top weighting might vary between different implementations.

From Table 3 it is seen that records with 50% overlap and Hanning weighting are almost statistically independent. This means that the same statistical

Table 3 BT_{eff} for Different Weighting Functions and Different Overlap^a

BT_{eff} per Record	0% Overlap	50% Overlap	75% Overlap
Rectangular	1	0.660	0.363
Hanning	1	0.947	0.520
Kaiser–Bessel	1	0.989	0.628
Flat top	1	1.000	0.995

^a The numbers for the Kaiser–Bessel and the flat-top weighting may vary between different implementations

accuracy can be obtained almost twice as fast using 50% overlap compared to 0% overlap.

2. Averaging using Hanning weighting with $66\frac{2}{3}\%$ ($\frac{2}{3}$), 75% ($\frac{3}{4}$), 80% ($\frac{4}{5}$) and so on overlap results in an overall weighting on the signal, which is flat (all samples are weighted equally). (See Ref. 2.)
3. In analysis of nonstationary signals, overlap facilitates the following of signal changes within the records.
4. When analyzing with low-frequency spans or with high resolution (zoom), where the records are relatively long, a faster display update rate can be achieved by using overlap.

3.3 Real-Time Analysis

In connection with FFT, real-time analysis is historically defined as the analysis of adjacent records, that is, with 0% overlap. This can be obtained when the calculation time equals the record length. The real-time frequency specifications of analyzers can thus be interpreted as a specification of the FFT processing speed.

From a more strict signal processing point of view, real-time analysis demands analysis of all the data all the time in all the frequency bands. When averaging using Hanning and $66\frac{2}{3}\%$ overlap, all the samples are weighted equally, implying real-time analysis in the more strict sense.

4 MULTICHANNEL APPLICATIONS

A number of important applications within signal and system analysis require the simultaneous measurement of multiple signals.

4.1 System Analysis

System analysis is often based upon simultaneous measurements of the input(s) and the output(s) of the system. The single input–single output situation is illustrated in Fig. 11; See Refs. 4–6.

If the spectrum (Fourier transform) of the input signal is $U(f)$, the spectrum of the output is $V(f)$, and the frequency response function of the system is $H(f)$, then $V(f) = H(f)U(f)$. The measurement noise $M(f)$ at the input is assumed to be uncorrelated with the input $U(f)$. Likewise, $N(f)$ is the measurement noise at the output and is assumed to be uncorrelated with the output $V(f)$. The measured input is $A(f) = U(f) + M(f)$, and the measured output is $B(f) = V(f) + N(f)$. Notice that the noise at output $N(f)$ could be due to other inputs not correlated with $U(f)$.

4.1.1 Cross Spectrum Together with the autospectra, the principal function for derivation of the system characteristics and quantification of the validity of the measurement is the *cross spectrum* between input and output.

Using FFT and linear averaging, the cross spectrum is estimated by

$$S_{AB}(f) = \frac{1}{N} \sum_{i=1}^N A_i^*(f) B_i(f) \quad (9)$$

where $A_i(f)$ and $B_i(f)$ are the complex spectra of the i th record, $A_i^*(f)$ is the complex conjugate of $A_i(f)$, that is, $A_i(f)$ with the phase inverted, and N is number of averages.

$A_i(f)$, $B_i(f)$, and $S_{AB}(f)$ have content at both positive and negative frequencies (see Fig. 8). The version of the cross spectrum that only has content at nonnegative frequencies, that is, where the content

Figure 11 System with a single input and single output.

at the negative frequencies is “transferred” to the corresponding positive frequencies, is called $G_{AB}(f)$; see Refs. 4 to 6.

The averaging is performed on complex numbers, and the influence of the noise terms $N(f)$ and $M(f)$ will be reduced with averaging since they are uncorrelated with $U(f)$ and $V(f)$. (This is because the phase between the noise signals and the input/output signals changes randomly from record to record.) Thus, $G_{AB}(f) \rightarrow G_{UV}(f)$ as $N \rightarrow \infty$. This is the essence of cross-spectrum averaging. The correlated parts of the signals, $U(f)$ and $V(f)$, are retained and the uncorrelated noise terms are reduced with averaging.

The phase of $G_{UV}(f)$ is the phase of the system, that is, the phase of the frequency response function $H(f)$. The autospectrum can be considered as the cross spectrum of the signal with itself.

4.1.2 Frequency Response Function The frequency response function can be derived from the measured autospectra, $G_{AA}(f)$ and $G_{BB}(f)$, and the cross spectrum $G_{AB}(f)$. Different estimators, such as $H_1(f)$, $H_2(f)$, and $H_3(f)$, are used depending upon the measurement situation and the content of noise. Table 4 lists the estimators and their use in situations with noise at input, noise at output, and with the same amount of noise at both input and output. If there is noise only at the output, $H_1(f)$ gives an unbiased estimate, and if there is noise only at the input, $H_2(f)$ gives an unbiased estimate. The more uncorrelated noise there is in the signals, the more averaging is required in order to minimize the random error. Figures for the random errors are found in Ref. 4.

In situations where the measurement bandwidth is too wide compared to the width of the resonance peaks in the frequency response function, the estimators will also be biased, and the error is called *resolution bias error*. It turns out that H_2 is less vulnerable to resolution bias errors at resonance peaks. Resolution bias is also referred to as *leakage*.

In the case of slightly nonlinear behavior, the H_1 estimator gives the best linear approximation of the frequency response function for the given input (excitation) signal.

4.1.3 Coherence The coherence function $\gamma^2(f)$ measures, on a scale from 0 to 1, the degree of linear relationship between the input and the output signals. The coherence is defined as

$$\gamma^2(f) = \frac{|G_{AB}(f)|^2}{G_{AA}(f)G_{BB}(f)} \quad (10)$$

Table 4 Use of Frequency Response Function Estimators in Situations with Only Noise at Input, Only Noise at Output, and with Same Amount of Noise at Both Input and Output

Measurement Situation	$H_1 = \frac{G_{AB}}{G_{AA}}$	$H_2 = \frac{G_{BB}}{G_{BA}}$	$H_3 = \frac{G_{AB}}{ G_{AB} } \sqrt{\frac{G_{BB}}{G_{AA}}}$
Noise at input, $M(f)$		Unbiased	
Noise at output, $N(f)$	Unbiased		
Noise at input and output and $G_{MM} = G_{NN}$			Unbiased

A coherence of less than 1 can be due to one or more of the following situations:

1. Uncorrelated noise in the input and/or in the output signal
2. Insufficient resolution (resolution bias error or leakage)
3. Nonlinear behavior of the system (if the input signal is random)
4. Delay in the system not compensated for in the analysis
5. Time-varying system

The coherence gives an indication of the validity and the quality of the frequency response function measurement. The reason for a low coherence often has to be investigated further. Low coherence does not necessarily mean a bad measurement. The influence of noise at the input or at the output, for example, can be eliminated by using a sufficient number of averages. Low coherence due to insufficient resolution or due to delays not compensated for is an example of poor-quality measurements (bad measurements).

4.1.4 Coherent Power, Noncoherent Power, and Signal-to-Noise Ratio These functions are used in situations where the low coherence is due to noise at the output.

$$\text{Coherent power} = \gamma^2(f)G_{BB}(f)$$

is a measure of the output $G_{VV}(f)$ of the system coherent with the input since there is no noise at the input [$M(f) = 0$]. The

$$\text{Noncoherent power} = [1 - \gamma^2(f)]G_{BB}(f)$$

is a measure of the noise at the output $G_{NN}(f)$. The

$$\text{Signal-to-noise ratio} = \gamma^2(f)/[1 - \gamma^2(f)]$$

is a measure of $G_{VV}(f)/G_{NN}(f)$, that is, the signal-to-noise ratio at the output.

4.1.5 Impulse Response Function The impulse response function is calculated by taking the inverse Fourier transform of the frequency response function. $H_1(f)$, $H_2(f)$, and $H_3(f)$ give the estimates $h_1(t)$, $h_2(t)$, and $h_3(t)$, respectively.

Other functions derived from the cross spectrum include

- Cross correlation
- Active intensity
- Phase-assigned spectrum

The phase-assigned spectrum of a signal is the autospectrum of the signal, with the phase of the cross spectrum between a reference signal and the signal

measured. It is, for example, used when determining the operating deflection shapes of vibrating structures.

5 ANALYSIS OF NONSTATIONARY SIGNALS

In the analysis of nonstationary signals, the resolution in both the time and the frequency domain is of importance. The resolution in the time domain should be fine enough to be able to follow the changes in the signal, and the resolution in the frequency domain should be sufficiently high to separate the different components in the spectrum.

Analysis using FFT provides a constant bandwidth analysis in which the time and frequency resolution is governed by the relation $T\Delta f = 1$, where T is the record length and Δf the spacing between the frequency lines. When a weighting function, such as the Hanning weighting, is applied on the time signal, the effective length of the analyzed time signal is shortened and the (noise) bandwidth in the analysis correspondingly widened, that is, $T_{\text{eff}}B \approx 1$ for each individual FFT (without averaging). The time resolution, given by T , or T_{eff} , is the same at all frequencies.

The individual FFT spectra, calculated with a certain overlap, can be stored in a multibuffer and displayed as a waterfall or contour plot. This is also referred to as short time Fourier transform (STFT). In Fig. 12, two analyses of a fast runup/down are shown. In the upper contour plot the record length $T = 125$ ms, that is, $\Delta f = 1/T = 8$ Hz, and in the lower contour plot the record length $T = 500$ ms, that is, $\Delta f = 2$ Hz. Hanning weighting and 66 $\frac{2}{3}$ % overlap is used. The rate of change of the fundamental frequency is approximately 18 Hz/s (1080 rpm/s; rpm = revolutions/minute). The record length of only 125 ms is short enough to follow the changes of the higher harmonics, and the different harmonic components (up to at least the 14th harmonic) are clearly detected, as seen in the upper plot. A record length of 500 ms, giving a higher frequency resolution ($\Delta f = 2$ Hz), allows for a better detection of the lower harmonics and interharmonics (where the rate of change in frequency is lower), whereas the higher harmonics are more smeared.

Another very useful technique for analysis of nonstationary signals consisting of sinusoidal components with varying frequencies and amplitudes is the order tracking technique, which is discussed in Section 6.

Wavelet analysis is another analysis technique used for nonstationary signals. This provides constant percentage bandwidth analysis, with resolution in the time domain governed by the wavelet applied in the analysis.⁷ The resolution in time increases with frequency corresponding to the increasing bandwidth. This is advantageous for signals having more rapid changes at the higher frequencies, as compared to the changes at the lower frequencies. Examples could be transient type response signals from systems with resonances having constant percentage damping. The more narrow resonances at low frequencies give longer responses to transient (impact) excitations than the

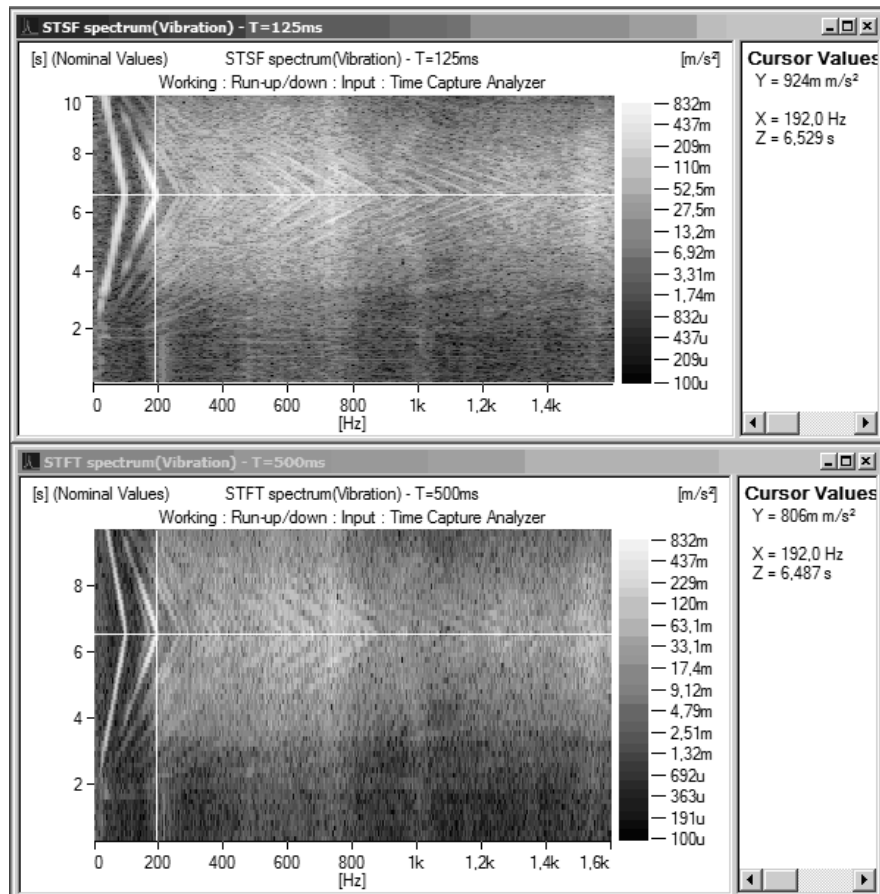

Figure 12 Analysis using FFT (STFT) of a fast run-up/down. In the upper contour plot the record length $T = 125$ ms, i.e., $\Delta f = 8$ Hz. In the lower contour plot the record length $T = 500$ ms, i.e., $\Delta f = 2$ Hz.

wider resonances at higher frequencies. Location of transient events in the time domain could thus be improved at the higher frequencies. This technique is covered in Chapter 49 of this book and thus is not further discussed here.

Standardized *octave and fractional-octave filters* are mainly used within the acoustical applications of nonstationary signal analysis. The classical examples are reverberation time measurements, passby analysis, and flyover analysis. The resolution in the time domain is given by the effective duration of the impulse response function of the filter and the averaging time in the detector.

Standardized octave and fractional-octave filters have characteristics that are optimized in the frequency domain (magnitude of frequency response function), and the effective duration of the impulse response of the filters can be several times $1/B$, where B is the bandwidth of the filter. This puts a limit on how far down in frequency it is possible to follow changes in a nonstationary signal, since the filter bandwidth decreases with decreasing center frequency.

The detector is, in most cases, for nonstationary signal analysis set to (running) exponential averaging with a time constant τ (corresponding to an equivalent averaging time of 2τ) for all the filters. The averaging time puts a limit on how fast changes can be followed in all the filter bands. The compromise is that the averaging time should be short enough to follow the changes in the signal and long enough to give sufficient statistical accuracy.

Taking reverberation time as an example, the detector time constant τ sets a limit on how short reverberation times can be measured. The minimum time constant of the system to be measured [i.e., the time it takes for the signal to decay a factor of e (or 8.7 dB)] is often set to 4τ , which means that the minimum reverberation time T_{60} is $6.9 \times 4\tau = 27.6\tau$ (T_{60} is 6.9 times the time constant of the system, since 60 dB/8.7 dB = 6.9).

The exponential detector responds faster to an increasing signal than to a decreasing signal. Analysis of the time-reversed decaying signal has the advantage of lowering the minimum time constant of the system

to be measured to 0.5τ , or the minimum reverberation time T_{60} to $6.9 \times 0.5\tau = 3.45\tau$. This is discussed in Refs. 8–10.

6 ANALYSIS TECHNIQUES USED FOR SIGNALS FROM ROTATING MACHINERY

6.1 Order Tracking

Noise and vibration signals from rotating machinery with varying speeds contain sinusoidal components with varying frequencies and amplitudes. The rotating parts in the machinery give rise to components at the fundamental rotating frequency and its harmonics and, in some systems, also at its subharmonics and interharmonics. The harmonics are referred to as the harmonic orders or simply the orders. Order tracking is an analysis technique specially designed to extract the information about the harmonic components of signals.

The instantaneous fundamental rotational frequency is typically measured by means of a tacho signal, and this is used to acquire signal values (samples) at times corresponding to *uniform shaft angle intervals* instead of at constant time intervals. Thus, there will be a fixed number of samples per shaft revolution independent of the rotational speed of the shaft, and an FFT will provide an *order spectrum* instead of a frequency spectrum. The orders will remain at fixed

positions in the order spectrum, independent of the rotational speed.^{11,12}

An order tracking analysis is, in the spectral domain, specified in terms of an order span Ord_{span} and number of lines N_{span} , resulting in an order spacing between the spectral lines of $\Delta\text{Ord} = \text{Ord}_{\text{span}}/N_{\text{span}}$. The corresponding record length, T_{rev} , in number of revolutions, is given by the order spacing as $T_{\text{rev}} = 1/\Delta\text{Ord}$. This is similar to the way the record length, T , is given by the frequency line spacing, Δf , as $T = 1/\Delta f$ for an ordinary FFT-based frequency analysis. An analyzer performing order tracking is often referred to as an order analyzer.

Figure 13 shows a frequency spectrum and an order spectrum measured on an electrical motor. The variation of the speed of the motor causes the frequency components to be smeared in the frequency spectrum (Fig. 13, top), and harmonic orders cannot be detected above 800 Hz. The order spectrum (Fig. 13, bottom) clearly reveals content in the harmonic orders and interharmonics up to order 20.

Order tracking is also used in the analysis of run-ups or run-downs (coast-downs) of machinery. Spectra are stored at predefined speed intervals, and the contour or waterfall plots of the spectra versus rotational speed give an overview of the content of harmonic orders and excitation of resonances during

Figure 13 Measurements of frequency spectrum (*top*) and order spectrum (*bottom*) of the vibration from an electrical motor.

the run-up or run-down. Figure 14 shows the analysis of the vibration signal from an electrical motor during a run-up. Frequency and order tracking analysis is performed on the signal. The contour plots of the frequency spectra and the order spectra versus rotational speed are shown in the upper and the lower graph of Fig. 14, respectively.

In the contour plot of the frequency spectra, the harmonic orders appear as oblique lines, while resonances (fixed frequencies) appear as vertical lines parallel to the rpm axis. In the plot of the order spectra, the orders appear parallel to the rpm axis, and resonances appear as hyperbolic curves.

In the frequency analysis, the time and the frequency resolution is constant during the run-up. In the above example, the record length of the FFT is $T = 250$ ms, corresponding to a spacing between the frequency lines of $\Delta f = 4$ Hz. In the order-tracking analysis each order spectrum is, in the above example,

based upon a record length of $T_{\text{rev}} = 20$ revolutions, corresponding to a spacing between the order lines of $\Delta \text{Ord} = 0.05$ orders. Thus, the records, measured in seconds, get shorter, and the bandwidths in the order spectra, measured in hertz, get wider, as the rpm increases. At each rpm (i.e., for each spectrum), the rms value of any order can be extracted and its variation as a function of rpm can be shown.

6.2 Signal Enhancement – Synchronous Time-Domain Averaging

This technique is used for extracting harmonic orders or periodic events buried in uncorrelated noise signals. It is used in connection with analysis using FFT and can be combined with order tracking. A synchronous trigger controls the recording of the time signals, and the averaging is performed in the time domain, resulting in an enhanced (averaged) time signal. The content

Figure 14 Contour plots of frequency spectra (*upper graph*) and order spectra (*lower graph*) as a function of rotational speed of the vibration signal from an electrical motor during a run-up.

of the uncorrelated noise is reduced through averaging, whereas periodic events or orders harmonically related to the synchronous trigger are retained. If the speed of the machinery varies, order tracking should be used to have the time records based upon shaft revolutions (shaft angle). As this technique is covered in Chapter 46, it is not discussed further here.

6.3 Other Analysis Techniques

There exist a wide variety of other analysis techniques. Discussion of these is out of the scope of this chapter. Two of them are mentioned below.

Cepstrum For detection of periodicities in spectra. A harmonic or a sideband family, for example, appear as a periodicity in the spectrum.

Envelope analysis For detection of periodic impacts, for example, due to faults in roller element bearings.

7 SIGNAL GENERATION AND EXCITATION TECHNIQUES

In system analysis (Fig. 11), an externally generated signal is often used for provision of a proper excitation of the system either through a shaker or a loudspeaker. The signal should be adapted to the analysis. A signal generator, therefore, is often built into the analyzer. This facilitates setting up of the generator to correspond to the analysis parameters (or vice versa) and also facilitates possible synchronization between the two.

A wide variety of signals can be used. Choice of the signal depends upon many factors, such as available test time, required accuracy, application, dynamic behavior of the system, and content of uncorrelated noise in the measured input and output signals. (See Table 5.)

Description of the system characteristics in terms of the frequency response function and the impulse response function is based upon the assumption of linear behavior of the system. For an ideal linear system, any type of excitation signal can be used, as long as there is energy at all the frequencies of interest in the signal. Systems encountered in real life exhibit a certain degree of nonlinear behavior, and the choice of an excitation signal and its amplitude can influence the result.

In this chapter, only a brief introduction of the most commonly used signals followed by a tabular

overview of some of the main features is given. More information is found in the references, including Refs. 5, 13, and 14.

Random Continuous random signal, which can be band limited to fit the frequency range of the analysis. The amplitude and phase at each frequency varies randomly from record to record in the analysis using FFT, and the H_1 estimator provides a best linear fit of the frequency response function in case of slightly nonlinear systems (see Refs. 4 and 5). White noise is most often used in connection with analysis using FFT.

In some acoustical applications where the analysis is performed using constant percentage bandwidth filters (fractional-octave filters), pink noise is often used. Pink noise has a power spectral density, which decreases proportionally with frequency (3 dB/octave), while the power in each of the filter bands is the same.

Pseudorandom Periodic repetition of a part of a random signal. As the period length is chosen to be equal to the record length in the FFT analysis, the signal has power only at frequencies coinciding with the frequency lines in the analysis. Rectangular weighting should be used and leakage is avoided in the analysis.

Burst Random Random signal gated with a user-definable gate width and repetition interval. With a gate (burst) sufficiently short to ensure the excitation and the response signals to be damped out at the end of the FFT record, rectangular weighting can be applied and leakage avoided in the analysis. A best linear fit of the frequency response function in case of a slightly nonlinear system can be obtained as for the random signal.

Sine Excitation at one frequency at a time. The amplitude can be controlled at different levels of excitation, facilitating analysis of the nonlinear behavior of systems. As the frequency is stepped or swept through the frequency range of interest, the test time usually becomes much longer than that for broadband signals.

Fast Sine Sweep A fast frequency sweep through a user-definable frequency range. By proper setting of the sweep rate the excitation and the response signals can be fitted into the record length of the FFT and leakage avoided in the analysis.

Table 5 Overview of Some Main Features of Most Commonly Used Signals

	Random	Pseudorandom	Burst Random	Sine	Fast Sine Sweep	Impulse
Control of frequency bandwidth	Yes	Yes	Yes	-	Yes	Limited
Leakage in analysis	Yes	Can be avoided	Can be avoided	Can be avoided	Can be avoided	Can be avoided
Best linear fit of slightly nonlinear systems	Yes	No	Yes	No	No	No
Crest factor	High	High	High	Low	Low	Very high
Signal-to-noise ratio	Fair	Good	Fair	Very good	Good	Poor
Test time	Short	Very short	Short	Long	Very short	Very short

Impulse A short-duration signal with a user-definable shape and length (and possibly repetition rate). The shape and the length of the pulse define the spectral content. The use of transient weighting on the response signal allows separation of the direct signal from the reflected signal in acoustical and electroacoustic systems.

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Data acquisition is concerned with the gathering of information from measurement sources such as sensors and transducers, which are used to convert the physical variables of interest into electrical signals. For noise and vibration applications, data acquisition plays an important role in both real-time monitoring and control and post process and analysis. The data acquisition must be performed correctly on sound and vibration signals in order to obtain correct results. A variety of interfaces and bus technologies, through which data streams pass, are used to save the data on storage media. Because of rapidly changing technologies, network-based data acquisition systems are increasingly coming into use. Descriptions of general computer-based data acquisition systems for sound recording technologies are readily available.

2 GENERAL CONSIDERATIONS OF DATA ACQUISITION EQUIPMENT

Traditionally, instruments, for example, oscilloscopes and digital multimeters, have been designed to perform particular functions. So they have limited capabilities and flexibilities. Users are seldom able to adjust or customize instruments. With the development of computer technologies, traditional instruments are becoming replaced by computer-based instruments because of the processing, interfacing, and networking power of computers. Moreover, decreasing prices of computers as well as peripherals, such as memory and hard drives, are also helping make computers a central part of testing and control. For data acquisition, since computers have hard drives of huge data storage capabilities, computers have advantages over traditional data logging equipment. Figure 1 illustrates the basic components of computer-based measurement and control systems.

Transducers, for example, microphones, force transducers, accelerometers, and proximity probes, convert sound pressure, force, acceleration, and

displacement measurements into electrical signals. Sensor outputs must often be conditioned to provide signals suitable for the measurement devices. Signal conditioning generally includes power supply, signal amplification, filtering, and/or isolation. The reader is referred to Chapters 35 and 43 for further discussion on signal conditioning. Since most sound and vibration signals are in analog form, the measurement devices then digitize the signals based on the requirements of particular applications. For some real-time analyzers and portable instruments, analyses, such as the fast Fourier transform (FFT), are also performed by hardware because the processing speed of hardware is generally greater than that of software. However, developments in software technology and the processing speeds of CPUs (central processing units) have made software fast enough in many applications.

Measurement software is the interface between users and the measurement hardware. Users can develop their own programs to design instruments. Measurement software generally contains three elementary components: configuration utilities, application programming interfaces (API), and driver engines. Software is also used to manage the data stream to the storage media and may be used to integrate the measurement system into a network.

The basic aim of data acquisition is to obtain signals correctly and reduce noise as much as possible. The selection of appropriate measurement hardware is based on a proper understanding of the signal properties and system requirements.

For computer-based data acquisition, the analog signal needs to be converted to digital. The signal is not only sampled discretely in time but quantized as well with discrete amplitude values. Because of sampling, the digital system is limited in frequency, which may cause some problems, such as aliasing. Quantization noise is another disadvantage of the digital system because the analog amplitudes have to be represented and stored as finite binary numbers in a

Figure 1 Basic components of computer-based measurement systems.

computer. So the sampling rate and resolution are two basic considerations of the analog-to-digital converter (ADC). To ensure correct data acquisition, one has to scrutinize the specifications of the measurement device, select an appropriate one and operate it carefully. The reader can refer to Ref. 1 for the related practical considerations in signal processing.

2.1 Sampling Rate

The well-known sampling theorem is usually stated as "the sampling rate must be at least twice the highest frequency." This statement is correct for baseband spectral analysis in which the bandwidth is from 0 Hz to the highest frequency limit. For better representation and reproduction of analog signals, a higher sampling rate, generally from three to five times the highest frequency, is recommended.

In more general cases, for example, zoom FFT, the bandwidth does not start from 0 Hz and can be narrow but in the high-frequency range. Then the statement in the last paragraph is not valid. A correct sampling rate should be defined based on the bandwidth rather than the highest frequency.² A sampling rate of 2.56 times the bandwidth is commonly used for zoom analysis.

2.2 Resolution

Resolution is the smallest amount of input signal change that an ADC can detect. Resolution can be represented by the number of bits of the ADC. After quantization, the analog values are rounded to finite possibilities determined by the resolution. These values are evenly distributed across the input range of the ADC. Obviously, the greater the number of bits used, the more accurate is the measurement. The signal-to-quantization noise ratio (SQNR) and the dynamic range also increase with the number of bits of the ADC.

There are two conventional analog-to-digital conversion methods: flash conversion and successive approximation. By involving the oversampling technique, the so-called sigma-delta ($\Sigma\Delta$) conversion, sometimes referred to as delta-sigma conversion, has been widely used in recent years. This technique can obtain high resolution with a simple antialiasing filter.^{3,4}

2.3 Input Range, Polarity, and Gain

The input range is the difference in voltage between the maximum and minimum voltage limits that can be measured by an analog input channel. The input range can be bipolar (for example, ± 10 V) or unipolar (for example, 0 to 5 V). The polarity of the output from the signal conditioner and the input of the measurement device must be matched. The gain is defined as the amplification or attenuation of the signal. Many measurement devices have multiple gains to select. A proper gain must be set to match the signal to the input range so that the best resolution can be obtained.

2.4 Analog Output

For use in modal analysis, we may need to generate white noise, pink noise, pure-tone, or swept-sine excitation. Active noise and vibration control applications also require the system to output voltage or current to

control the feedback loop. These can be done by the analog output channels on the measurement devices. Analog output is accomplished by using a digital-to-analog converter (DAC). Like the analog input, the resolution is determined by the number of bits. With techniques, such as FIFO (first in, first out) and DMA (direct memory access), high-speed updating can be obtained.

2.5 Digital Input/Output and Counter/Timer

Digital I/O (input/output) devices are commonly used in sound and vibration applications because some transducers output digital signals and the wide use of digital I/O in control systems. The common-mode noise and transient voltage spikes are two forms of interference in digital signals. If the signal is not properly conditioned, isolation is required on the data acquisition device. The voltage level is another consideration. Most digital I/O devices deal with 0- to 5-V TTL (transistor-transistor logic) and TTL-compatible CMOS (complementary metal-oxide-semiconductor) levels. Some devices work with 24-V levels, which are common in industrial applications.

Counter/timer devices are used for a wide variety of applications, such as frequency measurements and position measurements. For rotating systems, a counter can be used to receive digital tachometer pulses. The counter size and the maximum source frequency are two major considerations for a counter. The counter size, which is the highest number that the counter can count, is determined by the number of bits. A large dynamic range requires a large number of bits. The maximum source frequency determines the resolution of a counter, which is the speed of the fastest signal that the counter can count. For example, a 20-MHz counter cannot catch pulses less than 50 ns.

2.6 Number of Input and Output Channels

The signal sources should be studied before the measurements are taken to make sure the number of input/output channels is sufficient. For example, a microphone array system may have a large number of microphones.

The differential measurement systems will double the number of input channels of single-ended measurement systems. The differential measurement systems are commonly used when the unwanted noise level is very high. Input channels exist in pairs, as shown in Fig. 2. One line is the positive (+) input and carries both the signal and the noise. The other is the reference, or negative (−) input, and only carries the noise. Ideally, the difference between the lines is then the real signal. In signal-ended measurements systems, the reference is the ground. So an input only occupies one channel.

Generally there are two methods for multichannel data acquisition. The first is that all input channels have their own sample-and-hold circuitries but share the same ADC. The digitizing circuitry scans the channels assigned by the software by a technique known as multiplexing or switching. So they have to have the same sampling rates. And the highest sampling rate capability of the ADC is divided by the number of

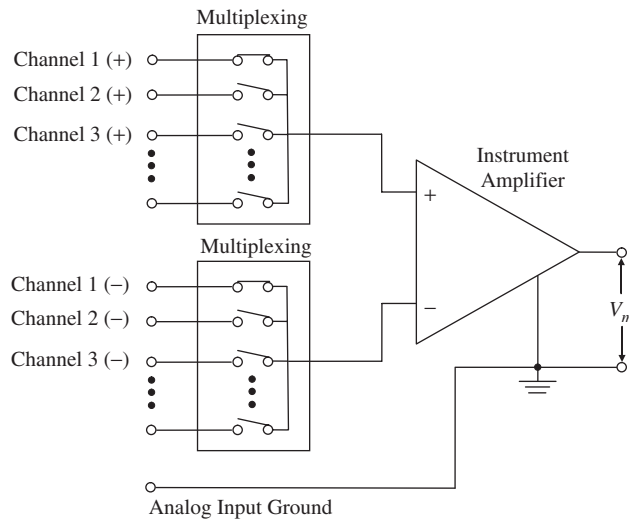

Figure 2 Schematic of a differential measurement system. V_m is the measured voltage.

scanned channels. The other method, used especially for real-time analyzers, is that each channel has its own ADC. Then the sampling rate and bandwidth are preserved. The reader can also refer to Chapters 40 and 42 for discussion on multiple signal systems.

2.7 Triggering and Synchronization

Many noise and vibration applications require precision synchronization and timing for data acquisition. For example, with a rotating system, the use of two perpendicular proximity probes requires synchronization of the measurement. Timing and triggering of the signals help to make the measurement synchronized.

An external event, known as a trigger, can be used to start and/or stop the acquisition of data. The use of triggers ensures that the data are acquired only during the time of interest. This saves hardware bandwidth and storage.

Triggers fall into two main types: digital and analog. The rising or falling edge of a TTL signal can be used as a digital trigger, as shown in Fig. 3. The level and slope of an analog signal can be used as an analog trigger. The data acquisition device should satisfy the triggering conditions that the application requires. For example, some applications require synchronization of both the analog input and analog output.

Some advanced synchronization techniques have been used for more sophisticated data acquisition systems. For example, the PXI (PCI extensions for instrumentation, see Section 3.6 of this chapter) chassis can provide the same clock signal for synchronization between all devices plugged into the chassis.

3 INTERFACE AND BUS TECHNOLOGIES

The data acquired by the data acquisition devices stream to the computer memory or hard drive to be

Figure 3 Rise and fall edges of a TTL signal.

analyzed, displayed, and stored through a certain interface, which is called a bus. Most traditional instruments have interfaces, such as the general-purpose interface bus (GPIB), RS-232, or the universal serial bus (USB), so that the data stored in these instruments can be transferred to computers. Data acquisition devices of different buses come in different forms and are suitable for different application requirements. For example, data acquisition boards plugged into desktop computers are used commonly in laboratories. However, PCMCIA (Peripheral Component MicroChannel Interconnect Architecture) cards for laptops and other portable equipment are more appropriate for measurements made in the field.

As modern computer technologies and fast buses, such as the USB, the FireWire bus, and the Ethernet, have entered the area of measurement and control, external devices have become easier to use than traditional internal personal computer (PC) buses. And the mixed I/O systems have begun to appear for use in

noise and vibration instrumentation. There are many textbooks available about buses.

When selecting data acquisition hardware, bus-related specifications, such as the transfer rate, the length of cable, and the extension capability, should be considered. Table 1 compares these features. The ISA/EISA (industry standard architecture/extended ISA) buses are not listed because they are no longer in use due to their low transfer rate. For new bus techniques, such as PCI-X, PCI Express, and 10 Gbit Ethernet, please consult Internet resources.

3.1 General-Purpose Interface Bus

The GPIB, or the Institute of Electrical and Electronics Engineers (IEEE) 488 bus, was developed originally to connect and control programmable instruments and provide a standard interface for communication between instruments from different manufacturers. GPIB is a digital 8-bit parallel communications interface capable of achieving data transfer of up to 8 Mbytes/s, through a shielded 24-line cable. The standard allows a maximum of 14 devices to be connected to a computer on the same bus. Many traditional instruments utilize a GPIB interface so that they can be connected together to establish a measurement and control network. There are three types of devices: listeners, talkers, and controllers. It is possible to have more than one controller on the bus, but only one can be active at a time. The reader can consult the literature⁵⁻⁸ for more details, such as data lines, handshake lines, interface management lines, and higher performance GPIB.

3.2 Serial Communication

The serial port sends and receives data bit by bit. The data type transmitted through the serial port is ASCII (American Standard Code for Information Interchange). The reader can refer to books on serial communication for connector pin descriptions, on how to use the registers, and for related information.^{9,10} However, note that the serial characteristics, including baud rate, data bits, stop bits, and parity, must match the ports that are connected.

Serial communication includes three standards: RS-232, RS-422, and RS-485. RS-232 is the most common serial standard, although it is being replaced by the USB. RS-422 and RS-485 use differential signals, as shown in Fig. 2, than the unbalanced signals

referenced to ground with the RS-232. So these two kinds of ports are less susceptible to noise. Table 1 shows that the RS-422 and RS-485 standards specify longer cables and wider bandwidths than those of the RS-232 and can be connected to multiple devices. Therefore, these two interfaces, especially the RS-485, are widely used to create networks in industrial applications that have more testing/control points and more serious environmental noise problems. And RS-232 works best for laboratory applications requiring a lower speed and less rugged connection.

The number of serial ports on a computer is limited. Generally a PC only has two RS-232 ports. If more serial ports are needed, a multiserial port board can be used to extend the capability of the system.

3.3 Universal Serial Bus

Although the USB was designed primarily to connect peripheral devices, such as keyboards, mice, printers, and digital cameras to PCs, it also provides an inexpensive but fast connection for data acquisition devices. The USB 1.1 specification has a maximum transfer rate of 12 Mbps. The USB 2.0 has a transfer rate of 480 Mbps. Devices that are connected through a USB port are external to PCs and hot pluggable, which means that it is convenient to add or remove a USB device without shutting down the computer. The bus is also capable of detecting a device automatically. That means that the user does not have to worry about configurations. This is called plug-and-play. The power supply available with the USB cable is an important benefit. Such devices automatically power down when not in use. Additionally, depending on the bus topology, up to 127 devices can communicate simultaneously through one USB port. By adding hubs, additional ports can be added to one host.¹¹

The USB ports have some shortcomings, however. First, the USB cables are not industrially graded. This has the potential to cause errors in noisy environments. Also there is no latching mechanism for USB cables. So the cables can be disconnected easily by mistake. USB cables are generally 1 or 2 m long. With the use of USB extenders, longer cables can be put together. Some manufacturers offer cascaded extenders.

3.4 FireWire

Like the USB, the FireWire also supports hot-plug, plug-and-play, and cable power. The FireWire is able

Table 1 Comparison of Buses

	Maximum Transfer Rate	Maximum Number of Devices	Maximum Cable Length
GPIB	8 Mbyte/s	14	20 m
FireWire	3.2 Gbit/s	64	100 m
PCI/PXI	133 Mbyte/s (for 32-bit bus)	Depends on the slot number	—
PCMCIA	20 Mbyte/s	Depends on the slot number	—
RS-232	230 kbit/s	1	15 m
RS-422	10 Mbit/s	10	1.2 km
RS-485	10 Mbit/s	32	1.2 km
USB 2.0	480 Mbit/s	127	30 m
VXI	160 Mbyte/s	Depends on the slot number	—

to deliver data through either a synchronous or an asynchronous mode. Synchronous transport guarantees that a transmission is completed within a given amount of time, but it does not guarantee that the transmission is free of error. On the other hand, asynchronous transport guarantees accurate delivery, and devices with urgent messages can be given priority over all other devices. As the IEEE 1394 ports are not built into Intel's PC peripheral chip set, a separate IEEE 1394 controller, typically a PCI board, is required to communicate with IEEE 1394 devices. The reader can refer to the IEEE standard and the two amendments.¹²⁻¹⁴

3.5 Virtual Machine Environment (VME) and VEM Extensions for Instrumentation

The Virtual Machine Environment (VME) bus, or IEEE 1014, possesses an excellent backplane, which is a circuit board containing sockets into which other circuit boards can be plugged, for building instrument systems with high transfer rates up to 160 Mbytes/s.^{15,16} The VXI bus (VME bus extensions for instrumentation) has been developed for portable applications and to provide a modular open standard for integration into the traditional GPIB test system and for stand-alone applications. A VXI system or subsystem consists of a VXI mainframe, an embedded controller, and VXI modules.

As the VME bus was designed specially for measurement purposes, VXI products are mainly used in high-end measurement applications, such as for military and aerospace tests. However, since the VME bus is not a part of modern computer architectures, VXI cannot take advantage of the developments in PC technologies. Its high price is another disadvantage for general-purpose test applications. For more information, the reader can consult the website of the VXI Bus Consortium, www.vxi.org.

3.6 Peripheral Component Interconnect and PCI Extensions for Instrumentation

The PCI is a local bus for high-end computers made to replace the ISA and EISA buses. The PCI bus transfers 32- or 64-bit data at a clock speed of 33 MHz and offers a theoretical maximum transfer rate of 133 Mbytes/s.

The PXI is a modular instrumentation platform designed specifically for measurement and control applications. PXI systems benefit from features such as compact and rugged packaging, open standard, large selection of modules, and low cost. Like VXI systems, PXI systems are comprised of three basic components: the chassis, the system controller, and peripheral modules. The chassis provides the PXI backplane, which includes the 133-Mbyte/s PCI bus and timing and triggering buses for accurate synchronization without additional cabling. The chassis has an extended number of slots compared to desktop computers. So plenty of modules, such as data acquisition and the real-time analysis devices, can be integrated into a multifunctional system. The controller plugged into the chassis is actually a high-performance computer with an operating system installed. Generally, it has all the interface

capability that a PC has, such as floppy drive, serial ports, parallel port, USB port, Ethernet interface, and so on. Connecting the monitor, keyboard, and mouse, a PXI system can work as a stand-alone and portable measurement and control system. The controller also can work under the remote control of a PC.

For more information, the reader can consult the website of the PXI System Alliance, www.pxisa.org.

3.7 Peripheral Component MicroChannel Interconnect Architecture

The PCMCIA bus is designed for laptop computers. So the use of PCMCIA measurement devices is a good choice for portable applications. The PCMCIA 2.1 release in 1993 specified a 16-bit bus interface with a theoretical maximum transfer rate of 20 Mbytes/s. In 1995 the PCMCIA 2.1 was enhanced to provide 32-bit operation at a clock speed of 33 MHz, like that of the PCI bus. The PCMCIA bus can serve testing and control devices, as well as memory card, network connection, and bus interface.

3.8 Ethernet

Ethernet, which is specified by IEEE 802.3, is widely used not only for networks but also for communications between instruments and computers. The most common transfer rates are 10 Mbit/s and 100 Mbit/s. With new gigabit Ethernet cards, higher transfer rates can be achieved. Twisted cables, such as the CAT 5 cable, can be used to connect devices at distances up to 100 m. However, fibers can be used for longer distance communication.

The wireless Ethernet specified by IEEE 802.11 is another emerging standard for measurement and control. The transfer rate of wireless Ethernet is much lower and decreases as the distance between the instrument and the computer increases. For example, the transfer rate of 802.11g is 54 Mbit/s within 20 m, and is only 1 Mbit/s at a distance of 125 m. However, it is very convenient to use wireless equipment to avoid requiring cabling.

4 NETWORK-BASED DATA ACQUISITION

Network-based measurement and control systems are important for distributed systems and harsh or toxic environments that are not safe for human beings. The conventional network based on serial communication and GPIB have been described in the previous section. These interfaces have limitations in both performance and flexibility.¹⁷ With the widespread adoption of technologies such as Ethernet, HTML (hypertext markup language), FTP (file transfer protocol), and wireless networks, along with software technologies, such as Visual Basic, Visual C++, and JAVA, measurements can be carried out over a local network, a company intranet, or the Internet.

For networked measurements, readers are recommended to study the seven-layer OSI (open systems interconnection) model.¹⁸ The network is composed of modules that can be software or hardware. The client/server model is a widely used architecture for

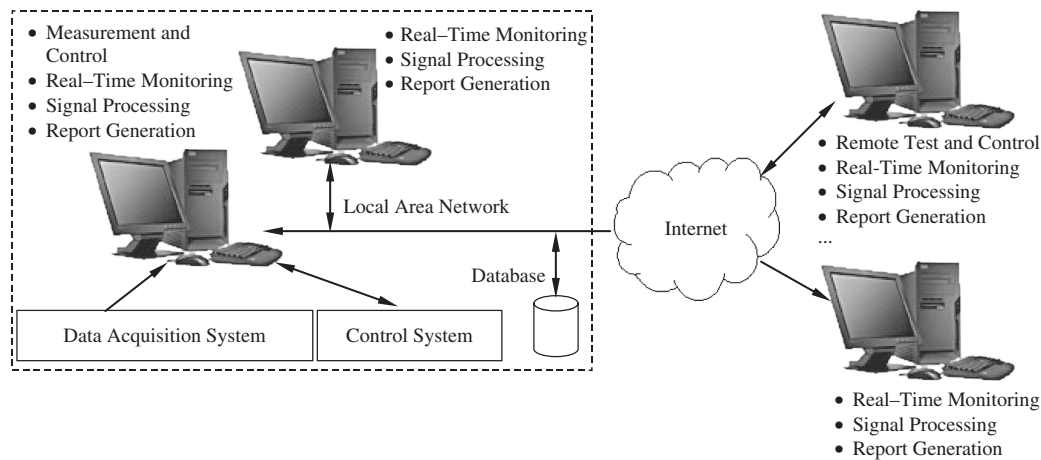

Figure 4 Client/server architecture for network-based test and control.

networked measurement and control and is illustrated in Fig. 4. The server can distribute data to clients. Clients can carry out remote control on the server. The other model is called peer to peer. At the measurement and control end, the data acquisition and control system can be connected to the server through different interfaces, such as PCI, GPIB, serial I/O, USB, IEEE 1394, and through wireless communication. Embedded systems are sometimes needed for certain measurement and control applications. An embedded system can be accessed from a host computer through the local area network (LAN). As the token ring network is now rarely used, Ethernet and wireless networks are becoming the most commonly used LAN architectures.

Some other LAN architectures may be appropriate for certain applications. For example, there are several kinds of industrial communication networks, such as Fieldbus and CAN (ISO 11898 Controller Area Network). They are designed for large-scale measurement and automation applications with multiple and distributed test and control points. The reader can consult the literature^{19,20} for more information.

4.1 Publishing and Sharing Data

Publishing data simply means generating a static Web report of test results so that the clients can access the report by using Web browsers. The most common method is to generate the report using HTML. Some corporations use a database to store the data and a Web interface for viewing the reports. Alternatively, the server can report the results by sending email. FTP is another way to access large files.

Sharing data is a dynamic process in which clients can access acquired data in real time. XML (extensible markup language) is a common standard for sharing data. XML generates a document that contains the acquired data. Because the document is built in a certain structure, it is easily accessible and readable by other applications through the network.²¹ Another

method used is the National Instrument DataSocket. DataSocket is a new network programming technology for data streaming over a network and can respond to multiple users without the complexity of the low-level TCP (transmission control protocol) programming.

Since multiple PCs can visit the same data server, additional signal processing may be performed on remote computers without degrading the performance of the test and control system. Meanwhile, a single PC can be connected to multiple data servers, which is convenient with distributed measurement and control systems.

4.2 Remote Control

With the data server running at the host computer, the control can be implemented from a remote computer on the network through a common Web browser. Although the acquisition is performed on the host computer, the remote user has complete control. The operation is the same as if the test were executed locally.

CHAPTER 42

SIGNAL PROCESSING

Allan G. Piersol
Piersol Engineering Company
Woodland Hills, California

1 INTRODUCTION

In general terms, signal processing is the science of extracting relevant information from measured data signals representing a phenomenon of interest. In the context of noise and vibration control, this usually means determining from measurements certain descriptive characteristics of the environment that will help identify the sources of the noise and vibration so that they can be reduced or controlled. The most important descriptive characteristic of common interest is the spectral content of the data, but other properties of the measured data may also be informative. Virtually all signal processing today is accomplished using digital instruments, but most transducers for measuring noise and vibration data produce analog voltage signals (see Chapters 38 through 41). Hence, the first step in digital signal processing is to translate the measured signals into a digital format for analysis. This chapter summarizes (a) analog-to-digital conversion procedures, (b) digital data storage and retrieval procedures, and (c) the basic digital computations involved in noise and vibration data analysis. The potential errors associated with all of these procedures and the computed results are also summarized.

2 ANALOG-TO-DIGITAL CONVERSION

An analog-to-digital converter (ADC) is a device that translates a continuous analog signal, which represents an uncountable set, into a series of discrete values (often called a time series), which represents a countable set. There are numerous types of ADC designs,¹⁻⁴ but the simplest type of ADC employs a sample-and-hold amplifier that translates the value of the analog signal at a specific sampling time into a constant voltage that is maintained until the

next sampling time. The series of constant-voltage steps are then compared to a repetitive ramp function produced by a sweep generator driven by a timing pulse generator or clock, and a binary counter is initiated at the start of each sweep cycle to produce a series of digital values representing the signal at discrete times.

Due to the merits of very high sampling rates relative to the highest frequency of interest in the data (oversampling to be discussed later), there is a movement toward ADCs with a different architecture that provide effective sampling rates in excess of 10^5 samples per second (sps). The most common type of ADC in this class is that referred to as the sigma-delta ($\Sigma\Delta$) converter,¹ which is schematically illustrated in Fig. 1. The key features of a $\Sigma\Delta$ converter are (a) the input of the analog signal through an integrator to a clock-driven comparator, which essentially acts as a one binary digit (one-bit) ADC, (b) the feedback of the one-bit comparator output through a one-bit digital-to-analog converter (DAC), which is then subtracted from the input analog signal, and (c) an averaging operation by a low-pass digital filter, which essentially increases the number of bits forming a digital value (the word size) in the digital output (see Refs. 4 to 6 for details on digital filters). Since the basic comparator and DAC operations are accomplished using a one-bit resolution, a very high initial sampling rate ($>10^7$ sps) can be achieved. The digital filter is then set to provide an output sampling rate after decimation that is substantially less than the initial one-bit sampling rate, commonly by a ratio of 256:1.¹ The frequency range of the final digital data can be varied by one of two procedures. The first is to lock the cutoff frequency of the digital filter to the initial one-bit sampling rate of the comparator so that the final sampling rate is controlled by simply varying the comparator sampling

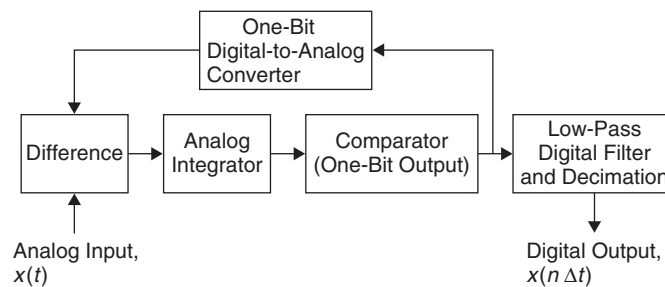

Figure 1 Schematic diagram of $\Sigma\Delta$ -type analog-to-digital converter.³

rate. The second is to fix the initial sampling rate of the comparator and then control the frequency limit and sampling rate of the final digital data by varying the cutoff frequency of the digital filter and the degree of decimation. In either case, this process of oversampling followed by low-pass digital filtering and decimation can be interpreted as increasing the effective resolution of the digital output by suppressing the spectral density of the digital noise in the output. Further details are presented in Section 2.3

Some of the important general considerations associated with the use of an ADC may be summarized as follows:

1. **Format** Many ADCs are integrated into more general signal processing equipment where the natural binary output of the converter is easily accepted. However, some ADCs operate as independent instruments. In this case, the output of the instrument is usually in the ASCII (American Standard Code Information Interchange) format, which allows the ADC output to be read directly by any computer program written in a common language, such as C or FORTRAN, or to drive terminal and register displays directly.
2. **Resolution** The output of an ADC is a series of digital words, each composed of w bits, which determine the number of discrete levels that can be used to define the magnitude of the input analog signal at discrete times. Hence, there is a round-off error introduced by the conversion, to be discussed later.
3. **Sampling Interval** In most cases, an ADC samples the input analog signal with a fixed sampling interval Δt , as illustrated in Fig. 2. However, there are sometimes situations where a variable sampling interval might be desired, for example, the sampling of an otherwise sinusoidal signal with a time-varying frequency. To accommodate such situations, most ADCs allow the sampling rate to be varied continuously with time as desired.
4. **Sampling Rate** At least two sample values per cycle are required to define the highest frequency in an analog signal. Hence, the sampling rate of the ADC, denoted by R_s , imposes an upper frequency limit on the digital

data. More important, any frequency content in the analog signal above this upper frequency limit will fold back and sum with the digital data at frequencies below this limit to produce a serious error, called aliasing, to be discussed later.

5. **Multiple Signals** Consider the situation where it is desired to convert m independent analog signals simultaneously into a digital format. If the available ADC has a sampling rate of $R_s \geq 2mf_c$, where f_c is the highest frequency in the analog signals, then all m of the analog signals can be converted with a single ADC by sequentially sampling the signals (often referred to as time-domain multiplexing). Of course, sequential sampling introduces a time-delay error of $\Delta t = 1/R_s$ from one signal to the next, but this time delay can be corrected when the digital sequence for each signal is recovered. On the other hand, because ADC devices are becoming relatively inexpensive, the use of parallel ADCs (one ADC for each analog signal) is becoming increasingly common.

2.1 Resolution

As mentioned before, the conversion of a continuous analog signal $x(t)$ into a digital sequence with a finite number of possible values separated by a magnitude interval Δx clearly imposes a resolution problem in the form of a round-off error. The resolution of the ADC is a function of the word size w (the number of bits) used to form each digital value in the ADC output, and may be defined in several ways, as follows:

1. **Range of Counts** The range of counts (sometimes called the span) is defined as the total number of possible digital values provided by the ADC output. Excluding zero, the range of counts (S) is given by

$$S = 2^w - 1 \quad (1)$$

2. **Dynamic Range** The dynamic range is defined as the ratio of the largest value (either plus or minus) to the smallest value provided by the ADC output. Assuming a mean value of zero and excluding the sign bit if used (one bit

Figure 2 Sampling of analog signal with a constant sampling interval.²

to define the sign polarity), the dynamic range (DR) is given in decibels (dB) by

$$\text{DR(dB)} = 10 \log_{10}(2^w - 1)^2 \quad (2)$$

$$\approx 6w \text{ for } w > 5$$

3. *Peak Signal-to-Noise Ratio.* The peak signal-to-noise ratio is defined as the ratio of the largest value (either plus or minus) to the standard deviation of the digital noise in the output of the ADC. The standard deviation of the digital noise is given by² $\sigma_n = \Delta x / \sqrt{12} = 0.289 \Delta x$. Assuming a mean value of zero and excluding the sign bit if used, the peak signal-to-noise ratio (PS/N) is given in decibels (dB) by

$$\text{PS/N(dB)} = 10 \log_{10}[12(2^w - 1)^2] \quad (3)$$

$$\approx 6w + 11 \text{ for } w > 5$$

4. *Signal-to-Noise Ratio.* The signal-to-noise ratio is defined as the ratio of the maximum standard deviation of the signal without clipping to the standard deviation of the digital noise in the ADC output. It follows that the signal-to-noise ratio is a function of the ratio of the peak value to the standard deviation of the analog signal being converted. Specifically, the signal-to-noise ratio (S/N) is given in decibels (dB) by

$$\text{S/N(dB)} = \text{PS/N(dB)} - 10 \log_{10}(P/\sigma_s)^2 \quad (4)$$

where P is the peak value of the signal, σ_s is the standard deviation of the signal, and PS/N (dB) is defined in Eq. (3). For example, if the signal is a sine wave, $(P/\sigma_s)^2 = 2$ (approximately 3 dB), so $\text{S/N(dB)} = \text{PS/N(dB)} - 3$. On the other hand, if the signal is random where clipping at three standard deviations is acceptable, $(P/\sigma_s)^2 = 9$ (approximately 10 dB), so in this case $\text{S/N(dB)} = \text{PS/N(dB)} - 10$.

A summary of the values given by Eqs. (1) through (4) for various common word sizes is presented in Table 1. Of course, the values in Table 1 are theoretical maximum values. In reality, there are various possible errors in the ADC that can reduce the effective word

size by perhaps one or two bits.² Furthermore, the values in Table 1 assume the full range of the ADC is used to convert the signal to a digital format. If the full range of the ADC is not used, then the various values will be less. Finally, the values in Table 1 assume the mean value of the signal is zero, which is generally true of noise and vibration signals.

2.2 Sampling Rate

The appropriate sampling rate for the conversion of a continuous analog signal into a sequence of discrete values is governed by the sampling theorem.² Specifically, given an analog signal with a bandwidth of B hertz and a duration of T seconds, the number of equally spaced discrete values that will describe the signal is given approximately by $n = 2BT$. Assuming the bandwidth B is from zero to an upper cutoff frequency of f_c , it follows that n = twice the number of cycles, that is, at least two samples per cycle are required to describe the signal. This defines an upper frequency limit for the digital data, commonly referred to as the Nyquist frequency, given by

$$f_A = \frac{R_s}{2} = \frac{1}{2\Delta t} \quad (5)$$

where R_s is the sampling rate in samples per second (sps), and Δt is the sampling interval in seconds. Any information in the analog signal at a frequency above the Nyquist frequency, f_A , will be interpreted as information at a frequency below f_A , as illustrated in Fig. 3. This phenomenon of information above f_A being folded back to frequencies below f_A is called aliasing. For data analyzed in terms of an auto- (power) spectral density function (to be defined later), the aliasing will distort the resulting spectrum of the data, as shown in Fig. 4. Note that there is no frequency limit on aliasing. Specifically, for any frequency f in the frequency range $0 \leq f \leq f_A$, the higher frequencies that will be aliased with f are defined by²

$$(2f_A \pm f), (4f_A \pm f), (6f_A \pm f), \dots \quad (6)$$

For example, if $f_A = 100$ Hz (corresponding to a sampling rate of 200 sps), then the data at 170, 230, 370, 430 Hz, and so forth will fold back and appear at 30 Hz.

Table 1 Range of Counts, Dynamic Range, and Signal-to-Noise Ratios for ADCs

Word Size (excluding sign bit)	Range of Counts	DR (dB)	PS/N (dB)	S/N (dB) Sine Wave	S/N (dB) Random
10	1,023	60	71	68	61
12	4,095	72	83	80	73
14	16,383	84	95	92	85
16	65,535	96	107	104	97
18	262,143	108	119	116	109

Figure 3 Frequency aliasing due to an inadequate sampling rate.²

Figure 4 Illustration of aliasing in the computation of an autospectral density function.²

Aliasing is a particularly serious error because once the analog-to-digital conversion is complete, (a) it may not be obvious that aliasing occurred, and (b) even if it is known that aliasing occurred, it is generally not possible to correct the data for the resulting error. It is for these reasons that aliasing must be avoided by low-pass analog filtering of the input signal to the ADC. The appropriate cutoff frequency for the analog low-pass filter (commonly referred to as the antialiasing filter) is dependent on the roll-off rate of the filter. However, assuming a roll-off rate of at least 60 dB/octave, a cutoff frequency of $f_c \approx 0.5f_A$ is desirable, although a cutoff frequency as high as $f_c = 0.8f_A$ may be used if the filter has a very high cutoff rate or there is little high-frequency content in the analog signal.

2.3 Oversampling

As noted earlier, modern ADCs often have an initial sampling rate that provides a Nyquist frequency f_A , as defined in Eq. (5), which greatly exceeds the upper frequency of interest in the data. In such cases, a relative simple analog antialiasing filter can be used where the cutoff frequency is at perhaps only 10% of the Nyquist frequency for the initial sampling rate. A very sharp cutoff low-pass digital filter can then be applied to the output of the ADC with a cutoff frequency f_c that is consistent with the upper frequency limit of interest in the data. So as to limit the number of data values that must be processed, the resulting digital data are decimated to provide

a final sampling rate with a new Nyquist frequency consistent with the upper frequency limit fixed by the digital filter. In effect, the low-pass digital filter acts as the final antialiasing filter. For example, assume it is desired to analyze noise and vibration data up to a frequency of 10 kHz. Further assume the cutoff frequency of the low-pass digital filter is set at 80% of the final Nyquist frequency. It follows that a final sampling rate of 25 kps is required. Finally, assume an oversampling rate of 256:1 is employed. An initial sampling rate of 6.4 MHz is then required. This process of oversampling followed by digital filtering and decimation will dramatically enhance the signal-to-noise ratio of the data.^{7,8} In the example above, even with only a one-bit initial conversion in the ADC, the effective word size of the final digital data values would be about $w \approx 16$ bits.

3 DATA STORAGE AND RETRIEVAL

In some cases, noise and vibration data are analyzed online using a special-purpose instrument where the first input stage is an ADC. In this case, the output of the ADC goes directly into an analysis algorithm, such as a digital filtering algorithm⁴⁻⁶ for instruments designed to compute $\frac{1}{3}$ octave band spectra, or a FFT algorithm^{2,5} for instruments designed to compute narrow bandwidth spectra. In other cases, however, the output of the ADC goes into some form of storage for later analysis. Furthermore, it is sometimes desired to retrieve the digital data from storage in an analog form.

3.1 Digital Storage

For digital data that will be analyzed in the near future, the most common approaches are to input the data into the random-access memory (RAM) or directly onto the hard disk (HD) of a digital computer. A direct input into RAM is generally the best approach if the number of data values is within the available RAM capacity. For those cases where the data analysis is to be performed at a later time, it is best to download the RAM into an HD, or record the data directly onto an HD. The speed that an HD can accept data is steadily increasing with time but is currently in excess of 40 Mbytes/s (for 16-bit sample values, 20 Msps). This is adequate to record the output of an ADC in real

time for most digitized noise and vibration signals. For long-term storage of digital data after the desired analyses have been performed, the data in RAM or HD can be downloaded into a removable storage medium such as a digital video disk (DVD) or a compact disk/read-only memory (CD-ROM). See Ref. 9 for details.

3.2 Digital-to-Analog Conversion

There are situations where it is desired to recover a continuous analog signal from stored digital data. This is accomplished using an digital-to-analog converter (DAC). A DAC is a relatively simple device where each digital value sequentially generates a fixed-level voltage signal, resulting ideally in a step function. In more advanced DAC designs, at least a linear interpolation routine is used to connect adjacent voltage values. In either case, there will be a discontinuity in the output voltage signal that produces a narrow bandwidth spurious signal at the sampling rate of the digital data and all harmonics thereof. These spurious signals, often called imaging errors,³ must be suppressed by analog low-pass filtering, analogous to the low-pass filtering used to suppress aliasing errors in analog-to-digital conversion. Since the low-pass antialiasing filter removed all information in the digital data above the filter cutoff frequency f_c , it follows that the cutoff frequency for the antiimaging low-pass filter on the output of the DAC should be at f_c or less.

4 DIGITAL DATA ANALYSIS COMPUTATIONS

There are various data analysis procedures that are required for applications to the noise and vibration control procedures detailed in this handbook. The most important of these data analysis procedures are now summarized. For clarity, the basic definitions for the various data analysis functions are given in terms of continuous time and frequency variables, and the mean value of the signal being analyzed is assumed to be zero.

4.1 Definitions

The most important descriptive functions of data for noise and vibration control applications are as follows:

1. *Root-Mean-Square (rms) Value* The rms value is a measure of the total magnitude of a periodic or stationary random signal $x(t)$. It is given by

$$\sigma_x = \lim_{T \rightarrow \infty} \left[\frac{1}{T} \int_0^T x^2(t) dt \right]^{1/2} \quad (7)$$

2. *One-Third Octave Band Levels* One-third octave band levels are given by the rms value, as defined by Eq. (7), of the output of a one-third octave bandwidth filter ($B \approx 0.23 f_0$ where f_0 is the filter center frequency), with the characteristics given by Ref. 10, versus the

filter center frequency. For acoustical data, the levels are usually presented in decibels (ref: 20 μ Pa).

3. *Fourier Transform* The Fourier transform over a finite time interval T is a frequency-domain function that provides the general frequency content of a periodic or stationary random signal $x(t)$. It is given by

$$X_T(f) = \int_0^T x(t) e^{-j2\pi ft} dt \quad (8)$$

Note that $X_T(f)$ is defined for both positive and negative frequencies and for infinitely long time histories will usually approach an infinite value as T approaches infinity.

4. *Line Spectrum.* A line spectrum (also called a linear spectrum) is a frequency-domain function that defines the frequency content of a periodic signal $x(t)$. It is given by

$$L_x(f_i) = \frac{2}{T_P} |X_{T_P}(f_i)| \quad i = 1, 2, 3, \dots \quad (9)$$

where $|X_{T_P}(f_i)|$ is the magnitude of the Fourier transform of $x(t)$ computed ideally over the period T_P of the periodic signal, as defined in Eq. (8) with $T = T_P$ and $f = i/T_P$, $i = 1, 2, 3, \dots$. Note that $L_x(f_i)$ and all other spectral functions to follow are defined for positive frequencies only.

5. *Autospectral Density Function* The autospectral density function (also called the power spectral density function, or simply the autospectrum or power spectrum) is a frequency-domain function that defines the spectral content of a stationary random signal $x(t)$. It is given by

$$G_{xx}(f) = \lim_{T \rightarrow \infty} \frac{2}{T} E[|X_T(f)|^2] \quad f > 0 \quad (10)$$

where $|X_T(f)|$ is the magnitude of the Fourier transform of $x(t)$ over the time interval T , as defined in Eq. (8), and $E[\]$ denotes the expected value operator, which implies an averaging operation.²

6. *Cross-Spectral Density Function* The cross-spectral density function (also called the cross spectrum) is a frequency-domain function that defines the linear correlation and phase as a function of frequency between two stationary random signals $x(t)$ and $y(t)$. It is given by

$$G_{xy}(f) = \lim_{T \rightarrow \infty} \frac{2}{T} E[X_T^*(f) Y_T(f)] \quad f > 0 \quad (11)$$

where $X_T^*(f)$ is the complex conjugate of $X_T(f)$, and $E[\]$ denotes the expected value operator, which implies an averaging operation.²

7. **Coherence Function** The coherence function (also called coherency squared) is a frequency-domain function that defines the normalized linear correlation (on a scale from zero to unity) as a function of frequency between two stationary random signals $x(t)$ and $y(t)$. It is given by

$$\gamma_{xy}^2(f) = \frac{|G_{xy}(f)|^2}{G_{xx}(f)G_{yy}(f)} \quad f > 0 \quad (12)$$

where $G_{xx}(f)$ and $G_{yy}(f)$ are the autospectra of $x(t)$ and $y(t)$, respectively, as defined in Eq. (10), and $|G_{xy}(f)|$ is the magnitude of the cross spectrum between $x(t)$ and $y(t)$, as defined in Eq. (11).

8. **Frequency Response Function** The frequency response function (also called the transfer function) is a frequency-domain function that defines the linear relationship as a function of frequency between two stationary random signals, $x(t)$ and $y(t)$. It is given by

$$H_{xy}(f) = \frac{G_{xy}(f)}{G_{xx}(f)} = |H_{xy}(f)|e^{-j\phi_{xy}(f)} \quad f > 0 \quad (13)$$

where $G_{xx}(f)$ is the autospectrum of $x(t)$, as defined in Eq. (10), $G_{xy}(f)$ is the cross spectrum between $x(t)$ and $y(t)$, as defined in Eq. (11), and $|H_{xy}(f)|$ and $\phi_{xy}(f)$ are the magnitude and phase, respectively, of $H_{xy}(f)$.

There are various other functions that can be helpful in some noise and vibration control problems, including:

1. Cross-correlation functions (given by the inverse Fourier transform of cross-spectral density functions), which can help locate noise and/or vibration sources^{2,11}
2. Coherent output power functions, which can identify the spectrum at a given measurement location of the contribution a single noise and/or vibration source among many other sources^{2,11}
3. Conditioned spectral functions, which can identify the correlated contributions of two or more noise and/or vibration sources²
4. Probability density functions, which can help identify the basic character of various noise and vibration sources^{2,12,13} (also see Chapter 13)

5. Cepstrum functions that can be helpful in determining the nature and source of certain complex periodic noise and/or vibration sources¹²
6. Wavelet functions that can be useful in the analysis of nonstationary random signals¹³ (also see Chapter 49).

4.2 Basic Digital Computations

The basic digital algorithms for the computations of the functions defined in the preceding section are summarized in the second column of Table 2. Note that the digital algorithms evolve directly from Eqs. (7) through (13) without the limiting operations and with $x(t)$ replaced by $x(n\Delta t)$; $n = 0, 1, 2, \dots, N-1$, where N is the number of sample values and Δt is the sampling interval given by $\Delta t = 1/R_s$. It follows that (a) $T = N\Delta t$, and (b) $f = k\Delta f$; $k = 1, 2, 3, \dots, N-1$. Important factors associated with the spectral computations in Table 2 are as follows:

1. The hat (^) over the designation of the functions denotes that these are estimates that will vary from one measurement to the next for random noise and/or vibration environments².
2. The digital form of the Fourier transforms, $X_{N\Delta t}(k\Delta f)$ and $Y_{N\Delta t}(k\Delta f)$, in the various spectral computations is commonly referred to as the discrete Fourier transform (DFT) and is normally computed using a fast Fourier transform (FFT) algorithm, which provides a dramatic increase in computational efficiency. See Refs. 2, 5, and 13 for details on FFT algorithms.
3. The autospectrum and cross-spectrum computations are accomplished by dividing the available data record into n_d contiguous segments, each of duration T , and computing the spectral function over each segment. The spectral results from the n_d segments are then averaged to approximate the expected value operation in Eqs. (10) and (11).²
4. The basic spectral window produced by a Fourier transform has a $\sin(x)/x$ characteristic with substantial side lobes that leak spectral components from one frequency to another. This leakage problem is commonly suppressed by tapering each segment of data prior to computing the transform. The process of tapering increases the effective bandwidth of the frequency resolution for spectral analysis, but this can be countered by the use of overlapped processing^{2,8,12} (also see Chapter 46).
5. Since the duration of a noise and/or vibration measurement will rarely correspond to an integer multiple of the period of even a single periodic component (often called a tone) in a noise and vibration environment, the exact frequency and magnitude of the components in a line spectrum for periodic components (tones) will be somewhat blurred, even with a

Table 2 Basic Digital Computations

Function Being Estimated	Basic Computation	Normalized Random Error, ε , or Standard Deviation, σ
rms value, $\hat{\sigma}_x$	$\left[\frac{1}{N\Delta t} \sum_{n=0}^{N-1} x^2(n\Delta t) \right]^{1/2}$	Periodic data, none Random data, $1/(2\sqrt{B_s T})$
Fourier transform, $X_{N\Delta t}(k\Delta f)$	$\sum_{n=0}^{N-1} x(n\Delta t) \exp\left(\frac{-j2\pi kn}{N}\right);$ $k = 0, 1, 2, \dots, N-1$	—
Line spectrum, $S_x(k\Delta f)$, for periodic signals (tones)	$\frac{2}{N\Delta t} X_{N\Delta t}(k, \Delta f) ;$ $k = 1, 2, \dots, [(N/2) - 1]$	None
Autospectrum, $\hat{G}_{xx}(k\Delta f)$, for random signals	$\frac{2}{(N\Delta t)n_d} \sum_{i=1}^{n_d} X_{iN\Delta t}(k\Delta f) ^2;$ $k = 1, 2, \dots, [(N/2) - 1]$	$\varepsilon = \frac{1}{\sqrt{B_s T}} = \frac{1}{\sqrt{n_d}}$
Cross-spectrum, $\hat{G}_{xy}(k\Delta f)$, for random signals	$\frac{2}{(N\Delta t)n_d} \sum_{i=1}^{n_d} X_{iN\Delta t}^*(k\Delta f) Y_{iN\Delta t}(k\Delta f);$ $k = 1, 2, \dots, [(N/2) - 1]$	Magnitude, $\varepsilon = \frac{1}{ \gamma_{xy}(k\Delta f) \sqrt{n_d}}$ Phase, $\sigma = \frac{(1 - \gamma_{xy}^2)^{1/2}}{ \gamma_{xy} \sqrt{2n_d}}$
Coherence function, $\hat{\gamma}_{xy}^2(k\Delta f)$, for random signals	$\frac{ \hat{G}_{xy}(k\Delta f) ^2}{\hat{G}_{xx}(k\Delta f)\hat{G}_{yy}(k\Delta f)};$ $k = 1, 2, \dots, [(N/2) - 1]$	$\varepsilon = \frac{\sqrt{2}[1 - \hat{\gamma}_{xy}^2(k\Delta f)]}{ \hat{\gamma}_{xy}(k\Delta f) \sqrt{n_d}}$
Frequency response function, $\hat{H}_{xy}(k\Delta f)$, for random signals	$\frac{\hat{G}_{xy}(k\Delta f)}{\hat{G}_{xx}(k\Delta f)};$ $k = 1, 2, \dots, [(N/2) - 1]$	Magnitude, $\varepsilon = \frac{[1 - \gamma_{xy}^2(k\Delta f)]^{1/2}}{ \gamma_{xy}(k\Delta f) \sqrt{2n_d}}$ Phase, $\sigma = \frac{(1 - \gamma_{xy}^2)^{1/2}}{ \gamma_{xy} \sqrt{2n_d}}$

tapering operation discussed in factor 4 above. However, there are algorithms that can be employed to extract the exact frequency and magnitude of each periodic component in a line spectrum.⁹ Also, tracking analysis, where the sampling rate of the ADC is tied directly to the source of a periodic component, can yield highly accurate frequency and magnitude results.¹²

4.3 Computations for Nonstationary Data

The basic digital computational algorithms in Table 2 assume the noise or vibration data being analyzed are stationary over the analysis duration $T = N\Delta t$. However, it is common for the data of interest in noise and vibration control problems to have time-varying (nonstationary) characteristics. There are rigorous analytical procedures for the analysis of nonstationary noise and vibration data, for example, the Wigner distribution for deterministic data and the instantaneous spectrum for random data.² Nevertheless, it is more

common in practice for analysts to evaluate nonstationary noise and vibration data by assuming the data are piecewise stationary. Specifically, a measurement of duration $T = N\Delta t$ is subdivided into a series of m contiguous segments, each of duration $T_s = N_s\Delta t$ where $T = mT_s$. The desired functions from Table 2 can then be computed sequentially over the m segments or by a running average over the entire measurement with a linear averaging time T_s . Procedures are available to select a segment duration or a running averaging time T_s that will minimize the total mean square error in the results,² but it is more common for analysts to select an appropriate value for T_s based upon past experience or trial-and-error procedures.^{9,12}

4.4 Statistical Sampling Errors

All of the computations for random signals summarized in Table 2 provide only estimates of the desired functions defined in Eqs. (7) through (13), as indicated by the hat (^) over the functions in Table 2. Specifically, the computed estimates, denoted generically as

$\hat{\phi}$, will involve a statistical sampling (random) error that can be defined in terms of a normalized random error (also called the coefficient of variation) given by

$$\varepsilon = \frac{\sigma_{\hat{\phi}}}{\phi} \quad (15)$$

where $\sigma_{\hat{\phi}}$ is the standard deviation of the estimate $\hat{\phi}$, and ϕ is the true value of the function being estimated. The normalized random errors for the various computed estimates in Table 2 are summarized in the third column in Table 2. Note that for computed phase functions, the random error is better described simply by the standard deviation of the phase estimate without normalization. Further note that the bandwidth B_s is the “statistical bandwidth” given by

$$B_s = \frac{\left[\int_0^\infty G_{xx}(f) df \right]^2}{\int_0^\infty G_{xx}^2(f) df} \quad (16)$$

For a uniform autospectrum over a bandwidth B , the statistical bandwidth is $B_s = B$.

The interpretation of the normalized random error is straightforward. Specifically, assuming the estimates have an approximately normal (Gaussian) distribution,² a normalized random error of $\varepsilon = 0.1$ means that about 67% of the estimates will be within $\pm 10\%$ of the true value of the function, and about 95% of the estimates will be within $\pm 20\%$ of the true value of the function.

The computed frequency-dependent estimates in Table 2 may also involve a bias (systematic) error that is dependent on the resolution bandwidth, Δf , as well as other factors. See Refs. 2 and 11 for details on these potential bias errors.

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Noise and vibration measurements are needed for a variety of purposes, including source and path identification, noise and vibration reduction of machinery, measurement of interior and exterior noise and vibration of vehicles, aircraft, and ships to name just a few applications. Noise and vibration measurements also need to be made in buildings and of the acoustical materials used in them to determine their acceptability for various uses. Periodic calibration of measurement systems and of the transducers used for the sound and vibration measurements is essential. Not only should transducer systems be calibrated before and after each time they are used but also checked annually by organizations, whose results are traceable to national and international standards. Some years ago, almost all measurements were made with analog equipment. Many analog instruments are still in use around the world. However, by using analog-to-digital conversion, increasing use is now made of digital signal processing to extract the required data. This is done either in dedicated instruments or by transferring measurement results onto computers for later processing by software. Sound power level measurement of machines is now required for predictions of sound pressure level or for labeling or regulatory purposes in some countries. Such sound power measurements can be made in special facilities (in anechoic or reverberation rooms—see Chapter 44—or with sound intensity equipment—see Chapter 45.) Special noise measurements are also required for new aircraft and vehicles and for monitoring traffic noise in the community and aircraft noise around airports. (See Chapters 119–130.)

2 MEASUREMENT QUANTITIES

2.1 Instantaneous Sound Pressure

Sound may be defined as a traveling disturbance in an elastic and inertial medium that can be perceived by a healthy human ear or instruments. It is important to consider that sound propagation is a three-dimensional process in space and that the sound disturbance varies with time. Thus, sound can be considered a four-dimensional field with several interrelated magnitudes that are dependant on the source, medium, and

boundary conditions. For the sake of simplicity, it is usually sufficient to assume a measurement process that involves the variation of the instantaneous pressure at a point in space; hence we will call this disturbance the instantaneous sound pressure $p(t)$ (measured in pascals).

2.2 Sound Pressure

The easiest measurable change of the medium is the variation in the local pressure from the ambient or undisturbed pressure. It is common practice to take its mean-square value and to calculate the root-mean-square (rms) pressure and call it the sound pressure $\langle p \rangle$. (See also Chapter 1.)

$$\langle p \rangle = \sqrt{\frac{1}{T} \int_0^T p^2(t) dt}, \quad (1)$$

where T is the time interval for the analysis or the period for periodic signals.

The sound pressure can be then expressed in decibels relative to a reference pressure p_0 as the sound pressure level. See Chapter 1.

$$L_p = 20 \log_{10} \frac{\langle p \rangle}{p_0}, \quad (2)$$

where p_0 is the reference pressure 20×10^{-6} Pa.

Along with this parameter of the signal under consideration, one more basic aspect has to be examined. That is, its level as a function of the frequency. With a simple approach this can be found by applying a Fourier transform to $p(t)$. However, more specific processes are generally applied to extract the pertinent data from the signal. (See Chapter 46 for more details on frequency analysis.)

2.3 Sound Power Level

A traveling wave implies the existence of a source radiating sound power, P , into the medium. The sound

Figure 1 Comparison of three sources with the same values of L_W but with different radiation patterns.

Note: The actual measurements were performed on one half of the circumference on the XY plane, and the overall sound power levels were adjusted to produce this comparison.

power level, L_W , is given in decibels by

$$L_W = 10 \log \left(\frac{P}{P_0} \right) \quad (3)$$

where P_0 is the reference sound power, 10^{-12} W.

The total sound power radiated by a source is independent of the directional characteristics of the source. These directional patterns are very important for noise control and noise propagation calculations because two sources with the same overall L_W may generate higher values of sound pressure level, L_p , in different directions as shown in Fig. 1. See Chapters 1, 44, and 45, for further discussion on directivity, sound pressure and vibration levels, and decibels.

2.4 Sound Intensity Level

The energy radiated by a source flows through a medium. The surface-normalized flow of this vector field in unit time represents the sound intensity, and normally the time-averaged intensity is the quantity

measured. The sound intensity \mathbf{I} is a vector quantity that is dependent on several factors, and it is simply related to the sound pressure p only under defined propagation conditions such as in a free field or in a reverberant field. This magnitude of the sound intensity \mathbf{I} is related to certain properties of the source, the medium, and the surroundings, and it can also be expressed in a logarithmic scale by

$$L_I = 10 \log \left(\frac{|\mathbf{I}|}{I_0} \right) \quad (4)$$

where I_0 is the reference sound intensity, 10^{-12} W/m².

2.5 Acceleration-Velocity-Displacement

Pressure, force, acceleration, velocity, and displacement are physically related and therefore mathematically related also. The magnitudes of these variables and their logarithmic equivalents play an important role in sound and vibration. Even though sound may also be referred to as a vibration, this latter term has a

wider meaning and represents a separate phenomenon. The main quantities studied in vibration analysis are:

- Force, $f(t)$
- Acceleration, $a(t)$
- Velocity, $v(t)$
- Displacement, $x(t)$

The magnitudes of these variables can be assessed as instantaneous, peak, peak to peak, average, rms, as a function of frequency, or weighted or unweighted within a certain frequency bandwidth.

Their equivalent logarithmic expressions are given by:

- Force level

$$L_f = 20 \log \left(\frac{\langle f \rangle}{f_0} \right) \quad (5)$$

where $\langle f \rangle$ is the rms value of the force (N), and f_0 is the reference force (10^{-6} N).

- Acceleration level

$$L_A = 20 \log \left(\frac{\langle a \rangle}{a_0} \right) \quad (6)$$

where $\langle a \rangle$ is the rms value of the acceleration (in m/s^2), and a_0 is the reference acceleration, 10^{-6} m/s^2 .

- Velocity level

$$L_A = 20 \log \left(\frac{\langle v \rangle}{v_0} \right) \quad (7)$$

where $\langle v \rangle$ is the time-averaged velocity (in m/s), and v_0 is the reference velocity, 10^{-9} m/s .

By analyzing these magnitudes or levels along the frequency axis and without considering the phase

Figure 2 Given an acceleration signal, a -20 dB/decade low-pass filter can be applied to obtain the velocity, and a -40 dB/decade low-pass filter to obtain displacement.

relationship between them, it is possible to correlate one magnitude with another, taking as a conversion factor the frequency of the signal under consideration (see Fig. 2).

We assume that $a(t)$ and $v(t)$ are defined as the acceleration and velocity, respectively. Consider their fast Fourier transforms (FFT):

$$\text{FFT}[a(t)] = A(\omega) \quad (8a)$$

$$\text{FFT}[v(t)] = V(\omega) \quad (8b)$$

$$V(\omega) = \frac{1}{j\omega} A(\omega) \quad (9)$$

At each frequency, the time-averaged and magnitude values of the velocity and acceleration are related by:

$$v(t) = \frac{1}{2\pi f} a(t) \quad (10)$$

In an analogous manner, we can write

$$x(t) = \frac{1}{(2\pi f)^2} a(t) \quad (11)$$

3 TYPES OF SIGNALS AND PROPER MEASUREMENT TECHNIQUES

Usually, it is not possible to directly measure any of the physical variables discussed above or their equivalent levels. However, it is possible to obtain equivalent representative electrical signals by means of the correct transformation of the sound and vibration events through the proper transducer mechanisms and algorithms, as shown in Chapters 35, 36, and 37. With carefully chosen transducers, these electrical signals will represent the scaled and transformed original magnitudes of the variables accurately.

The analysis must be carried out on a signal that will represent the actual magnitude under consideration, and some of the analysis transformation and domains are shown in Figs. 3 and 4. It is possible to apply different measurement techniques, which depend on several properties of the signal and which are adequately suited to extract the desired information. Processing techniques applied to the captured signal, whether in real time or postprocessed forms will include FFT, IFFT, convolution, de-convolution, filtering, cepstral techniques, correlation, and time-delay spectrometry. See Chapter 46 for a more detailed explanation of data analysis and signal classifications.

4 TYPICAL MEASUREMENT CHAIN

A typical measurement system block diagram is depicted in Fig. 5. In the digital era the measurement chain has evolved from (i) a quite complicated acquisition and processing system, which was always undergoing changes in hardware to (ii) a flexible and small processing unit fed by an analog transducer and

preamplifier or signal conditioner through an analog-to-digital (A/D) converter. Therefore, the original diagram has been replaced by a more straightforward and flexible digital signal processor (DSP) that performs different calculations with only the need to run a different binary code for each step of the measurement. There are three key parts in the diagram in Fig. 5.

Transducer and Preamplifier These are the most critical stages that affect the quality of the measurement and provide the basis for the accuracy, dynamic range, and noise floor of the system.

A/D Converter With a sampling rate (SR) and a conversion depth of N bits, this is the link between the analog continuous-time real-world and its digital discrete time representation. The continuously varying voltage across its input is correlated with a sampled and quantized signal in the digital domain. During this conversion the signal will be limited by the SR and the conversion depth or resolution, N bits, as follows (see Chapter 42):

The theoretical upper frequency range is

$$f_{\max} = \frac{\text{SR}}{2} \quad (12)$$

The actual frequency range will depend on the antialiasing filter used, and it may be reduced by as much as 20%.

The theoretical dynamic range (DR) is

$$\text{DR} = 10 \log_{10}(2^{N \text{ bits}} - 1)^2 \quad (13)$$

With this process we will find that the conversion error is $\pm \frac{1}{2}$ LSB (least significant bit), and this error is inherent in the use of an analog-to-digital converter. This fixed amount of uncertainty will have a greater affect on the lower than the higher level components of the signal. This implies that the precision will also be limited by the linear-to-log conversion process, and the variable error of this linear uncertainty will cause a large effect on the low levels of signals. The impact of this quantization error on a 16-bit A/D converter is shown in Fig. 6. More information on A/D converters can be found in Chapter 42.

Digital Signal Processor The digital signal processor needs to be properly programmed to comply with the parameters required in the particular measurement standard being used. The processor can be replaced by specific software running on a personal computer. Care must be taken to verify that the algorithm performs the required process effectively and accurately. Note that most software packages that are commercially available are expensive and specifically designed to operate with certain acquisition devices.

5 UNCERTAINTY AND REPEATABILITY

Taking a sound level meter as an example (Fig. 5, modified to use a microphone as a transducer), the signal will pass through several stages in the

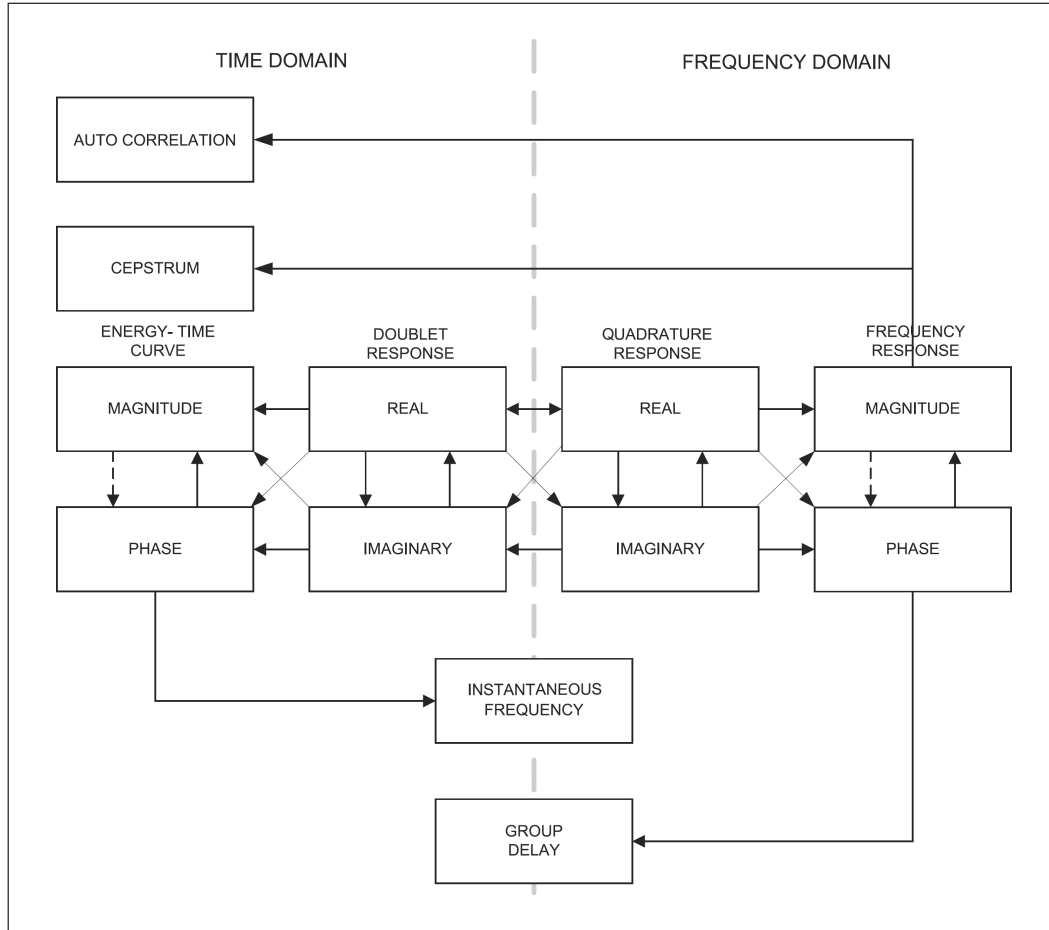

Figure 3 Measurement domains shown. Different transformations between time and frequency domains.

measurement chain. Every stage in this process will produce a certain uncertainty and, therefore, will increase the error in a particular measurement. A typical and expected uncertainty will occur with the class of instrument being used according to the standard being utilized [usually the International Electrotechnical Commission (IEC) or the American National Standards Institute (ANSI)]. However, there are other kinds of uncertainties that can be attributed to different causes in the measurement process and not to the instrument itself. In the case of a noise assessment with L_{Aeq} as the measured parameter, we can represent the final uncertainty σ_{tot} as

$$\sigma_{tot} = \sqrt{R^2 + X^2 + Y^2 + Z^2} \quad (14)$$

The final calculation, according to Table 1, yields $\sigma = 1.5$ dB for class 1 instruments and $\sigma = 2.25$ dB for class 2. As a consequence, measurements made of L_{Aeq} of a stable and continuous stationary random source, at close range to minimize propagation uncertainty

and with favorable meteorological conditions without residual noise, will represent the actual noise value within these uncertainty margins.

All this analysis is valid using a single parameter as a reference such as L_{Aeq} . In the case of a more complicated measurement environment, the accuracy of the measurement must be evaluated accordingly.

It is often required to evaluate energy sums instead of energy averages, for example, in the case of industrial noise dosage. In such a measurement, errors will accumulate creating an even higher uncertainty. A similar problem will arise when the spectrum has to be evaluated because of the linear distortion involved in the microphone and filter responses and variations in linearity as a function of frequency. All this is valid within a certain range of operation where a linear approximation can be applied, provided no overload occurs in the measurement chain. This procedure can be expanded to take into account more parameters, which are specifically related to the class of instrument, as can be seen in Table 2.

Figure 4 Typical domain transformation and calculation options on a two-channel FFT.

As a reference, the least attainable uncertainty with a laboratory-grade instrument will be, according to laboratory standards, within the uncertainty bounds of Table 3.

5.1 Other Factors

If we follow the correct calibration procedure and keep an updated and traceable calibration record every year

or two, we can be assured of obtaining proper readings with an instrument, within the accuracy established by the instrument classification (see Chapters 51 and 52).

Microphones are affected by environmental agents, electromagnetic interference, and vibration. Electronics are quite susceptible to thermal noise and electromagnetic fields. The extent to which these effects may

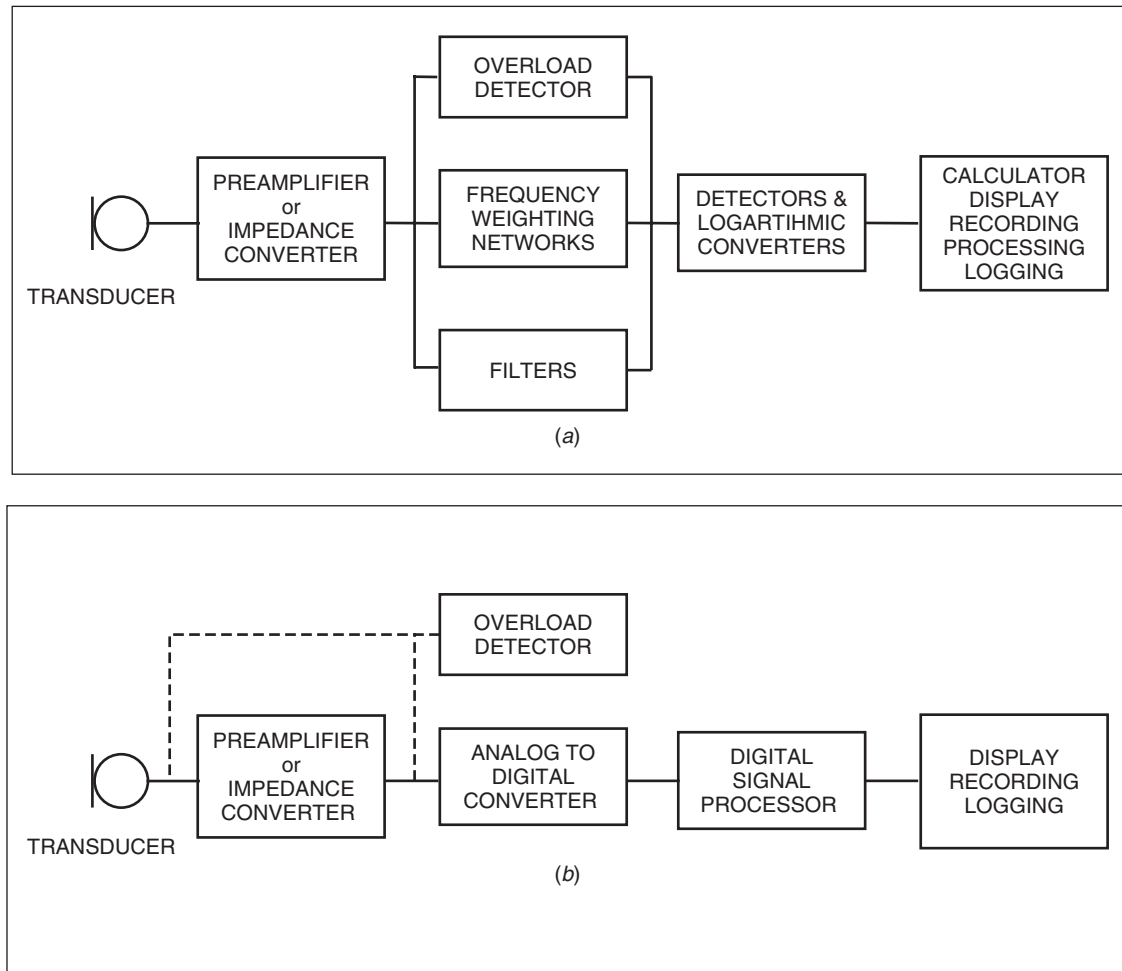

Figure 5 (a) Block diagram of a typical analog measuring system. (b) In its digital counterpart, an analog-to-digital converter is implemented after the preamplifier or impedance converter and a DSP produces all of the measurement procedure.

Table 1 Uncertainty of Measurement Based on Individual Uncertainties

Standard Deviation of Reproducibility ^a (dB)	Standard Uncertainty Due to Operating Conditions ^b (dB)	Standard Uncertainty Due to Weather & Ground Conditions ^c (dB)	Standard Uncertainty Due to Residual Sound ^d (dB)	Combined Standard Uncertainty σ (dB)	Expanded Measurement Uncertainty (dB)
1.0	X	Y	Z	$\sqrt{1.0^2 + X^2 + Y^2 + Z^2}$	$\pm 2\sigma$

^a Different operator, different equipment, same place, and everything else constant; see ISO 5725.¹ If class 2 sound level meters or directional microphones are used, the value will be larger.

^b To be determined from at least 3, preferably 5, measurements under repeatability conditions (the same measurement procedure, the same instruments, the same operator, the same place), and at a position where variations in meteorological conditions have little influence on the results. For long-term measurements, more measurements will be required to determine a repeatable standard deviation.

^c The value will vary depending upon the measurement distance and the prevailing meteorology. In this case $Y = \sigma_m$. For long-term measurements different weather categories will have to be dealt with separately and then combined together. For short-term measurements, these variations may add considerably to the measurement uncertainty.

^d The value will vary depending on the difference between measured total values and the residual sound.

modify their performance depends on several factors. It is important to check the manufacturer’s specifications about these effects, which will vary from brand to brand. As a guideline, Figs. 7 and 8 show the temperature and the ambient pressure versus frequency sensitivity variations, which are typical of a commercial microphone.

6 REVERBERATION TIME MEASUREMENTS

The acoustical characteristics of a room are one of the main issues in noise control and architectural acoustics.

In the first case, we can focus on how these modify the amount of energy transmitted to the receiver, and in the second one we can include several measurable descriptors of a room to evaluate the quality of the perceived field. See Chapters 4 and 103 for more detailed information.

Among many of these parameters related to the acoustical quality of a room (see ISO 3382-1997⁹), the determination of the reverberation time (RT) is frequently the main goal of acoustical measurements. The reverberation time is defined as the time taken for the sound field energy to decrease to 1/1,000,000

Figure 8 Effect of ambient atmospheric pressure variation on the sensitivity vs. frequency curve of a high-quality microphone. (Courtesy Bruel & Kjaer.)

of its original value, after the source has been turned off. It is useful to determine not only the most important characteristics of the acoustical environment but also to indirectly quantify the absorption coefficient measured in a reverberation chamber. This parameter—also known as the Sabine absorption coefficient—is widely used in architectural acoustics, noise control, and the acoustical characterization of material properties.

There are several methods available for the measurement of the RT. Each of these has differences compared with the others in terms of instrumentation, measurement time, and accuracy. There are two standard procedures:

1. Interrupted noise method
2. Integrated impulse response method

Some general considerations apply to both of these methods:

1. The standard frequency range of interest covers the octave or one-third octave bands beginning at 88 Hz and finishing at 5657 Hz. This range can be extended by one octave at the upper and lower frequency limits.*
2. Both the source and the microphone have to be omnidirectional and comply with certain specifications.

*Current laboratory test facilities for materials provide reliability and proper diffusion only to roughly 88 Hz and larger rooms should be constructed to allow this change to be globally representative, although there are some exceptions to this limit.

3. There should be no distortion or overload in the measurement chain.
4. All the characteristics of the instrument are clearly defined in the standard used.
5. There is a minimum distance from the source to the microphone as given by Eq. 15:

$$d_{\min} = 2\sqrt{\frac{V}{cT}}, \text{ m} \quad (15)$$

where V is the room volume, m^3 ; T is the expected reverberation time, s, and c is the speed of sound in air, m/s.

6. The number of measurement points will influence the final result as well as the bandwidth and the RT. The uncertainties r_{20} and r_{30} can be evaluated for T_{20} and T_{30} with Eqs. (16) and (17), respectively (in accordance with ISO 5725-2¹):

$$r_{20} = \frac{370}{\sqrt{BNT_{20}}} \% \quad (16)$$

$$r_{30} = \frac{200}{\sqrt{BNT_{30}}} \% \quad (17)$$

where B is the filter bandwidth (0.71 for octave and 0.23 for one-third octave band filters, multiplied by f_c), N is the number of averages preformed, f_c is the center frequency of the measured values of T_{20} and T_{30} . See Table 4 for definitions.

7. The number of measurement positions will depend on the coverage method chosen and

Table 4 Determination of RT Parameters from the Decay Curve

Parameter	Starting Point	Finishing Point	Extrapolating to T_{60}
T_{20}	5 dB (below start of decay)	25 dB (below start of decay)	X 3
T_{30}	5 dB (below start of decay)	35 dB (below start of decay)	X 2

on the area or seating capacity in the case of an auditorium, and it should be selected as follows:

- Low coverage: in cases where only an assessment of the amount of room sound absorption is required for noise control purposes
 - Normal coverage: in cases where measurements are needed to verify whether the acoustical performance of a building meets specific design requirements
- Any special consideration regarding furniture, draperies, carpets, occupation, and the like should be clearly noted.
 - The temperature and humidity should be measured and recorded because they greatly affect the sound absorption of the air at high frequencies.

7 MEASUREMENT DESCRIPTORS FOR NOISE

It would be a great achievement to understand and represent noise signals and their underlying processes with a single index and to correlate this index with human perception of noise. Unfortunately, this is not the case, although there are a number of descriptors that are useful in evaluating the effects of noise. See Chapters 1, 34, and 106 for further discussion on measurement descriptors.

In the following definitions the word *signal* is understood to be a general term with a broad meaning ranging from sound to noise and including single, multiple, and complex noise sources, either fixed or moving.

Instantaneous Sound Pressure— $p(t)$ It is the most accurate descriptor of the signal under investigation, representing the variation of the sound pressure as a function of time. The definitions of the following parameters are based on this descriptor, $p(t)$.

Time-weighted and Frequency-weighted Sound Pressure Level This is the sound pressure level weighted in time and frequency with certain specific functions. The most common time weightings are slow, fast, and impulse. The most common frequency weightings are A, C, or no weighting.

Peak Sound Pressure Level— L_{peak} This is the logarithmic expression of the frequency-weighted or unweighted maximum instantaneous value of the sound pressure $p_{\text{max}}(t)$.

$$L_{\text{peak}} = 10 \log_{10} \left(\frac{p_{\text{max}}}{p_0} \right)^2 \quad (18)$$

Equivalent Continuous Sound Pressure Level— $L_{\text{Aeq}T}$ This is denoted as $L_{\text{Aeq}T}$ and represents the continuous steady-state A-weighted sound pressure level, which would have the same total mean energy as the signal under consideration in the same period of time T :

$$L_{\text{Aeq}T} = 10 \log_{10} \frac{1}{T} \int_0^T \left[\frac{p_A(t)}{p_0} \right]^2 dt \quad (19)$$

where $p_A(t)$ is the instantaneous A-weighted sound pressure, p_0 is the reference sound pressure, $20 \mu\text{Pa}$, and T is the analysis time period.

N Percent Exceedance Level— $L_{K_1K_2N\%,T}$ This is the time- and frequency-weighted sound pressure level exceeded for $N\%$ of the time interval under consideration; K_1 is the weighting filter of the instrument and K_2 is the time weighting constant. $L_{\text{AS}50,15 \text{ min}}$ is the A-weighted sound pressure level, slow time-averaged, exceeded 50% of the considered time of 15 min. See also Chapter 34.

Sound Exposure Level (SEL) This index applies to discrete noise events and is defined as the constant level that, if maintained during a 1-s interval, would deliver the same A-weighted sound energy to the receiver as the real time-varying event. We can understand this as a $L_{\text{Aeq}T}$ normalized for $T = 1 \text{ s}$:

$$\text{SEL} = 10 \log_{10} \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} \left[\frac{p_A(t)}{p_0} \right]^2 dt \quad (20)$$

where $p_A(t)$ is the instantaneous A-weighted sound pressure, p_0 is the reference pressure of $20 \mu\text{Pa}$, t_0 is the reference time, in this case 1 s, $t_2 - t_1$ is the time interval, which is made long enough to include the whole part of the event under consideration.

Perceived Noise Level (PNL) This index is based on perceived noisiness and applies to aircraft flyovers. The determination of the annoyance caused by aircraft noise is quite complicated and is explained in the aircraft noise measurement section of this chapter. See also Chapter 34.

Specific Descriptors for Community Noise The process of measuring and correlating noise with annoyance is a key issue in environmental impact studies. Descriptors are needed, not only to assess current situations but also to plan noise control measures and long-term noise impacts on the

population. This process encompasses not only the measurement of noise levels but also the understanding of the characteristics of noise events and the noise source in terms of level, frequency content, number of repetitions, and period of the day of occurrence. The noise events can be described in the following terms:

Single Events Events such as the passby of a motorcycle, the flyby of an aircraft, or a blast at a mining facility are defined as single events. These will be described in terms of sound exposure level with frequency weighting, maximum sound pressure level with time and frequency weighting, and peak sound pressure level with frequency weighting along with the event duration.

Repetitive Single Events These may be considered as the sum due to the reoccurrence of multiple individual events. In this case the measurement should be based on the descriptors for a single event plus the amount of repetitions that take place.

Continuous Sound The sound will be termed continuous when the sound pressure level generated is constant, fluctuating or slowly varying in the time interval of the analysis. A good descriptor for this category of noise is the A-weighted equivalent continuous sound pressure level.

If A-weighted sound pressure levels are not sufficient to assess the noise impact, more parameters need to be included to adjust and better correlate the measured event with annoyance. These parameters include corrections for period of day, tonality, low-frequency content, and impulsiveness. These adjustments should be consulted in the applicable standard or current legislation being used.

Composite Whole-Day Rating Levels Composite rating levels are used widely, and a substantial amount of research has been conducted, and standards and legislation have been written using this descriptor for guidance as the main assessed parameter. Two examples of this rating are the day–night rating level and day–evening–night rating level. See also Chapters 1, 34, and 106 for further discussion on these descriptors.

Day–Night Rating Level (L_{Rdn})

$$L_{Rdn} = 10 \log \left[\frac{d}{24} 10^{(L_{Rd} + K_d)/10} + \frac{24-d}{24} 10^{(L_{Rn} + K_n)/10} \right] \quad (21)$$

Day–Evening–Night Rating Level (L_{Rden})

$$L_{Rden} = 10 \log \left[\frac{d}{24} 10^{(L_{Rd} + K_d)/10} + \frac{e}{24} 10^{(L_{Re} + K_e)/10} + \frac{24-d-e}{24} 10^{(L_{Rn} + K_n)/10} \right] \quad (22)$$

where d is the number of daytime hours, e is the number of evening hours, L_{Rd} is the daytime rating level including adjustments for sources and characteristics, L_{Rn} is the nighttime rating level including adjustments for sources and characteristics, L_{Re} is the evening rating level including adjustments for sources and characteristics, K_d is the daytime adjustment, K_e is the evening time adjustment, and K_n is the nighttime adjustment.

The duration of each time period varies from country to country and both the period duration, and adjustment corrections for each period decided by the local noise authority must be used correctly.

8 VEHICLE NOISE MEASUREMENT

The measurement of noise and vibration in moving vehicles is a complicated process that involves several separate procedures (see Chapter 83). However, the emission of traffic noise produces an environmental impact in urban and suburban surroundings that can be measured. If the emission level of vehicles complies with certain established noise levels, the impact of this emission based on traffic density, street layout, and countermeasures can be evaluated and controlled beforehand. To evaluate this noise impact prior to the introduction of a new vehicle to the market, a reliable measurement method is needed. There are two main measurement methods used to establish the emission level of a vehicle considering it as a single source:

- Stationary
- Dynamic Accelerating

In general, these methods are not used to determine whether the noise is caused by aerodynamic, tire, engine, exhaust, gear box, or transmission sources.

Taking into account that in urban areas vehicles spend much of the time accelerating or decelerating, the standard procedure is to use engineering methods to obtain a quantitative measure of this emission level. The accelerating noise is often the peak noise output of many vehicles, and vehicle noise tests based on the full acceleration mode are commonly made. This procedure is covered fully in several national and international standards.

8.1 Measurement Instruments and Procedures

It is suggested to use an IEC 61672² type 1 sound level meter and to set the instrument detectors to A-weighting and fast time weighting. The required discrete-time interval to analyze the noise variation as a function of time is 30 ms. Critical distances and environmental conditions should be noted and reported as well as the vehicle speed with the precision stated in Table 5.

Special considerations are required to ensure hemispherical directivity with a divergence not more than ± 1 dB. To achieve this, ISO 10844¹⁰ defines a specific procedure and ground plan to conduct the tests (see Fig. 9). Optimally, the A-weighted noise level floor should be not less than 10 dB below and if possible

by aircraft and airports, and (2) long-term influence of exposure to noise in residential zones nearby or affected by airports and its operations.

People are less tolerant of the noise generated by the flyover of an aircraft when they are indoors rather than outdoors, even if the same event with the same acoustical energy is involved. It does not seem to matter that sound pressure levels indoors are attenuated by the structure of the building. Therefore, the annoyance perceived by a listener is not a simple matter, and that is the reason for creating an accurate way to measure perceived noise levels.

9.1 Measurement Method and Calculation Procedure

To quantify the perceived noisiness, the noise generated (1) by single aircraft movements and (2) by multiple aircraft operations at airports are treated separately. In each case several international standards fully describe the recommended procedures for the noise measurements. See also Chapter 34.

The measurements of the noise generated by aircraft are made following these recommendations:

- A type 1 measurement device is required.
- The height of the microphone must be 1.2 m above the ground.
- The ground must be an acoustically hard surface.
- The microphone must be positioned in a straight line with the aircraft path.
- There must not be any obstacle in the area near the measurement station.
- At no time must the wind speed, measured 10 m above the ground, exceed 5 m/s, and the microphone must be properly protected from the wind.
- The measurement system must be calibrated before and after use.

The data obtained must be processed and preferably digitally recorded for later analysis to obtain the time history and spectrograms. To make a rough approximation to the perceived noise levels, it is only necessary to obtain the spectrum histories. To calculate an accurate result, however, which can be validated by international standards, it is necessary to obtain the time history as well. The frequency spectrum history must be obtained at least every 0.5 s throughout the measurement period. The results are analyzed in one-third octave bands from 50 to 10,000 Hz.

To calculate the perceived noise level (PNL), the sound pressure levels must first be converted into perceived noisiness (PN). The PN is given in “noys,” and the relationship between the sound pressure level L_p , PN, and PNL is shown in Fig. 10. The 1-noy curve is the minimum value of the sound pressure level L_p required to disturb a person’s tranquility. The PN or N , can be calculated with the following expression:

$$N = n_{\max} + 0.15 \left(\sum n - n_{\max} \right) \quad (23)$$

Once the PN value has been obtained, it is converted into PNL, which is a logarithmic expression relative to a reference PN value (2 noys in this case):

$$L_{PN} = 40 + \frac{10 \log_{10} N}{\log_{10} 2} \quad (24)$$

In the case that the spectrum curve obtained is not smooth and the differences between bands are greater than 3 dB, because of tonal components, a correction must be applied. This correction factor is called the tone correction C and is obtained by complicated calculations that are described in the relevant standard.

The PNL values corrected by this method are tone-corrected values and are named TCPNL. These corrections are shown in Fig. 11. However, TCPNL values are only spectrum corrected and do not take into account the fact that the annoyance caused by the noise depends not only on the frequency content of the event but also on the duration of the exposure. So a time correction should be applied as well. This time-corrected value L_{EPN} is defined as follows:

$$L_{EPN} = 10 \log_{10} \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} 10^{L_{TPN}/10} dt \quad (25)$$

where L_{TPN} is the tone-corrected value of L_{PN} .

The effective perceived noise level, or EPNL, is the most accurate and accepted measurement unit for aircraft overall perceived noise level. However, PNL and TCPNL values will not always satisfy the need for a reliable noise figure. For the validation of the measurement, other variables such as aircraft conditions, the wind direction, and other meteorological aspects must be documented.

The equations given so far are only applicable to individual events. Equations (26) and (27) apply to multiple events through equivalent perceived noise levels (EQPNL) and A-weighted equivalent noise levels (EQANL):

$$L_{PNeq} = 10 \log_{10} \left(\frac{1}{T} \sum_i 10^{L_{EPN_i}/10} \right) \quad (26)$$

and

$$L_{AeqT} = 10 \log_{10} \left(\frac{1}{T} \sum_i 10^{L_{AX_i}/10} \right) \quad (27)$$

where i indicates the number of the event and T is the duration of the measurement in seconds.

9.2 Aircraft Noise Application Case

The calculation of EPNL requires a large amount of gathering and processing of data. In this example, measurements were made with a type 1 digital sound level meter capable of data recording, avoiding the need for an additional recorder. The time increment

Figure 10 Graph showing the relation between noys and PNL.

Figure 11 Tone correction (C) for PNL used to obtain TCPNL values.

Figure 12 A-weighted sound pressure level versus time data clearly showing the noise peak due to the aircraft flyover above the microphone location.

Figure 13 Example of a nonsmooth aircraft noise spectrum where a tone correction must be applied.

(k) was taken as 0.5 s for a period of 43 s, which involved the aircraft takeoff. (See Figs. 12, 13, and 14.)

10 ACOUSTIC IMPEDANCE MEASUREMENTS

Impedance tubes are used to measure the acoustical properties of materials. Acoustic impedance is an important material characteristic directly related to the material sound absorption. The acoustic impedance can be measured quickly and evaluated with only a small sized sample of the material, without the need for a reverberation chamber. Impedance tube measurements are quite adequate for production tests and research and development measurements in the laboratory.

The setups of Figs. 15, 17, and 18 are used to determine the plane wave impedance of a material sample. The material impedance and the absorption and reflection coefficients can be determined by two main methods:

1. Measuring the standing-wave ratio with one microphone
2. Measuring the complex sound pressure transfer function between two microphones

10.1 Standing Wave Ratio Method (One Moving Microphone)

Consider a pipe of cross-sectional area S and length L . Assume that the pipe is terminated at $x = L$ by a mechanical impedance Z_m and is driven by a piston at $x = 0$. A movable probe microphone is used to measure the sound pressure of the standing-wave pattern inside the tube (Figs. 15 and 16). Provided the excitation is harmonic and of sufficiently low frequency to ensure only plane waves propagate, the following equation holds true for the pressure:

$$p(x, t) = A e^{j[\omega t + k(L-x)]} + B e^{j[\omega t - k(L-x)]} \quad (28)$$

Figure 14 Difference between A-weighted L_p TCNLT, and EPNLT.

Figure 15 Setup for measuring the normal incidence acoustic impedance of a material.

Figure 16 Dashed line: Test sample has zero sound absorption. Solid line: test sample has sound absorption greater than zero. Notice that the sound pressure amplitude at an antinode is $A + B$ and the sound pressure amplitude at a node is $A - B$.

where \mathbf{A} and \mathbf{B} are complex constants imposed by boundary conditions at the two ends of the pipe.

Therefore the particle velocity can be expressed as

$$\mathbf{u}(x, t) = \frac{1}{\rho c} (\mathbf{A} e^{j[\omega t + k(L-x)]} - \mathbf{B} e^{j[\omega t - k(L-x)]}) \quad (29)$$

and the acoustic impedance Z_A of the plane waves inside the tube is

$$Z_A(x) = \frac{\rho c}{S} \left\{ \frac{\mathbf{A} e^{j[\omega t + k(L-x)]} + \mathbf{B} e^{j[\omega t - k(L-x)]}}{\mathbf{A} e^{j[\omega t + k(L-x)]} - \mathbf{B} e^{j[\omega t - k(L-x)]}} \right\} \quad (30)$$

The mechanical load impedance at $x = L$ can be expressed in terms of the acoustic impedance of the waves:

$$Z_m = S^2 Z_A = \rho c S \left(\frac{\mathbf{A} + \mathbf{B}}{\mathbf{A} - \mathbf{B}} \right) = \rho c S \left(\frac{1 + \mathbf{B}/\mathbf{A}}{1 - \mathbf{B}/\mathbf{A}} \right) \quad (31)$$

Rewriting \mathbf{A} and \mathbf{B} as follows:

$$\mathbf{A} = A, \quad \mathbf{B} = B e^{j\theta} \quad (32)$$

and substituting into Eq. (31) gives

$$Z_m = \rho c S \left[\frac{1 + (B/A) e^{j\theta}}{1 - (B/A) e^{j\theta}} \right] \quad (33)$$

it is possible to extract from this equation the mechanical impedance, knowing the ratio of incident and reflected waves and the phase angle θ . Substituting Eq. (32) into (28) and solving to obtain the modulus and average value of $p(t)$, we obtain

$$P = |p(t)| = \sqrt{(A+B)^2 \cos^2[k(L-x) - \frac{\theta}{2}] + (A-B)^2 \sin^2[k(L-x) - \frac{\theta}{2}]} \quad (34)$$

This sound pressure distribution along the x -axis is shown in Fig. 16 for two cases.

It is not possible to measure A and B separately but only $A + B$ and $A - B$. Defining the standing-wave ratio (SWR) as

$$\text{SWR} = \frac{A + B}{A - B} \quad (35)$$

the sound power reflection coefficient R is

$$R = \frac{B}{A} = \frac{\text{SWR} + 1}{\text{SWR} - 1} \quad (36)$$

and it is possible to find a simple relation with the absorption coefficient for normal incidence:

$$\alpha_n = 1 - R^2 = \left(\frac{\text{SWR} + 1}{\text{SWR} - 1} \right)^2 \quad (37)$$

10.2 Transfer Function Method (Two Fixed Microphones)

This method (see Fig. 17) is based on the measured frequency response function between two microphones H_{12} , which implies separating the incident (p_i) and reflected (p_r) sound pressures and their respective Fourier transforms P_i and P_r , by computing the complex reflection coefficient, R , at the measurement surface. The complex impedance Z can be calculated from these data. The experimental setup for this procedure is shown in Fig. 18.

The frequency response function in the frequency domain, H_{12} , is defined as

$$H_{12} = \frac{P_2}{P_1} = \frac{P_{2i} + P_{2r}}{P_{1i} + P_{1r}} \quad (38)$$

where P is the Fourier transform of $p(t)$, P_{ni} is the Fourier transform of the sound pressure due to the

Figure 17 Impedance tube measurement setup. The microphones are located at positions 1 and 2, separated by a distance s . The sample is located at a distance ℓ from microphone 2.

Figure 18 Experimental setup for sound absorption measurement of material samples with tube, microphones A and B, and frequency analyzer.

incident waves (i) at microphone n , and P_{nr} is the Fourier transform of the sound pressure due to the reflected waves (r) at microphone n , where n is either 1 or 2 and refers to the microphone considered (see Fig.17).

Taking into account that

$$\begin{aligned} H_{12i} &= \frac{P_{2i}}{P_{1i}} & H_{12r} &= \frac{P_{2r}}{P_{1r}} \\ R_1 &= \frac{P_{1r}}{P_{1i}} & R_2 &= \frac{P_{2r}}{P_{2i}} \end{aligned} \quad (39)$$

For microphone 1 the following holds true:

$$R_1 = \frac{H_{12} - H_{12i}}{H_{12r} - H_{12}} \quad (40)$$

provided that only plane waves propagate in the tube and that the transfer functions H_{12i} and H_{12r} are e^{-jks} and e^{+jks} , respectively. Multiplying the calculated reflection coefficient by $e^{j2k(l+s)}$ to calculate its value at $x = 0$, R can be expressed as

$$R = e^{j2k(l+s)} R_1 = -e^{j2k(l+s)} \left(\frac{H_{12} - e^{-jks}}{H_{12} - e^{jks}} \right) \quad (41)$$

The normal incidence sound absorption coefficient is $\alpha = 1 - |R|^2$, and the surface-specific acoustic impedance ratio Z is

$$Z = \frac{Z_s}{\rho_0 c} = \frac{1 + R}{1 - R} \quad (42)$$

where Z_s is the specific acoustic impedance of the surface.

10.3 Application of Impedance Tube Measurements

The sound absorption and mechanical properties of several different road surfaces have been studied in a recent research project at Auburn University. The absorption coefficient of dense and porous road surfaces was measured in the laboratory using core samples with 10- and 15-cm diameter impedance tubes. The 15-cm tube allows the absorption of a large core sample surface to be determined, but only up to a frequency of about 1250 Hz. The 10-cm tube allows the absorption coefficient to be determined up to a frequency of about 1950 Hz. See the setup in Fig. 18. The two different diameter impedance tubes were also mounted vertically on some of the same pavement types and the absorption coefficient of these pavement types was measured in this way too.

The impedance tubes consist of a metal tube (of either 10- or 15-cm internal diameter) with a loudspeaker connected at one end and the test sample mounted at the other end. The loudspeaker is enclosed and sealed in a wooden box and is isolated from the tube to minimize structure-borne sound excitation of the impedance tube. Usually, a steel backing plate is fixed tightly behind the specimen to provide a hard sound reflecting termination. Plane waves are generated in the tube using broadband white noise from the noise generator of a Bruel & Kjaer PULSE system. The same tube can be used to measure the sound absorption coefficient of samples in situ. In such a case, the tube is mounted vertically to the surface under study and a seal is made with some sealant between a metal collar at the lower end of the tube and the sample.

Two identical microphones are mounted in the tube wall to measure the sound pressure at two longitudinal locations simultaneously. The PULSE

system is used to calculate the normal incidence absorption coefficient α by processing an array of complex data from the measured frequency response function. Figure 19 illustrates the experimental setup for the test equipment.

The working frequency range is determined by the dimensions of the setup. The lower frequency limit depends on the microphone spacing. For frequencies lower than this limit, the microphone spacing is only a small part of the wavelength. Measurements at frequencies below this limit will cause unacceptable phase errors between the two microphones. The low-frequency limit was set at 200 Hz in these experiments. The upper frequency limit depends on the diameter of the tube:

$$f_u < \frac{Kc}{d} \quad \text{Hz} \quad (43)$$

where c is the speed of sound (in m/s), d is the tube diameter (in m), and K is a constant equal to 0.586 in the International System (SI) of units.

For frequencies higher than f_u , the sound waves in the tube are no longer plane waves. For the 15-cm diameter tube, the theoretical upper frequency limit is 1318 Hz. However, the plane wave assumption did not appear valid for frequencies higher than 1250 Hz. So for these tests, the working frequency range was set to be from 200 to 1250 Hz. For the 10-cm diameter tube, the theoretical upper frequency limit for the tube is 1978 Hz. For some thin samples whose thicknesses were 2.54 and 3.84 cm, the first absorption peak occurs higher than 1250 Hz. So the smaller 10-cm tube can be used for thin samples. One result is shown in Fig. 20. It is observed that there is generally fair agreement between the results obtained with the two different diameter tubes. The larger diameter tube allows larger

Figure 19 Experimental setup for sound absorption measurements of asphalt road surface samples with impedance tube, microphones A and B, and frequency analyzer. Note the road surface samples and metal spacers. Two 10-cm diameter tubes lie horizontally on the table. One 15-cm diameter tube can be seen standing vertically on the left.

samples to be tested, which because of the non-uniform sample surfaces gives greater confidence in the measurements. The larger diameter tube, however, does not allow measurements to be made above about 1200 Hz. Since the A-weighted sound pressure level tire noise peaks at about 800 Hz for vehicles at highway speeds (see Chapter 86) porous road surfaces of the order of 4 to 5 cm in thickness would appear to be a good choice. Many more experimental results of the sound absorption measurements of road surface samples are presented in Ref. 11 and 12. Space limitations preclude their presentation here.

11 ACCELEROMETER PRINCIPLES AND VIBRATION MEASUREMENTS

Accelerometers have become the most commonly used devices to measure vibration. (See Chapters 35 and 37.) The device mainly responsible for transforming the vibration into electrical signals is the piezoelectric accelerometer, which has an output proportional to the acceleration acting on its body. The key material used to build them is a piezoelectric crystal loaded by a seismic mass to enhance its sensitivity. Seismic mass theory is given in Chapter 35. Typical loading conditions are compression and shear as shown in Fig. 21.

The calculation of related velocity and displacement parameters can be done either in an analog electronic stage through integration or in the digital domain with algorithmic processing of the data gathered in almost real time. Taking into account that

acceleration, velocity, and displacement are mathematically related through derivatives and integrals (see Fig. 2 and Chapter 1), a typical measurement versus frequency graph will have a certain slope, and this slope will accentuate certain regions of the frequency plot. Therefore, it is usually common practice to select the vibration parameter that gives the flattest measured frequency response to optimize the dynamic range of the measurement chain.

There are three main characteristics of accelerometers that have to be carefully chosen in accordance with the particular measurement being made:

- **Mass.** If the accelerometer mass is large compared to the mass of the vibrating system, it will alter its natural frequency or load the system. The mass of the accelerometer should be

Figure 23 Time history of 450 wiper runs, $\frac{1}{12}$ th octave vibration testing of a small windshield wiper motor showing the burn-in settling and wear of the softer parts on the first runs reflected by the high variability of certain frequency bands. (Courtesy interPRO and Dakar Ingeniería Acústica.)

no more than one tenth of the vibrating system's mass. (See Fig. 16 in Chapter 35 and the related discussion there for a more complete description of the effects of mass loading of accelerometers.)

- **Charge Sensitivity** If the seismic mass of the accelerometer is increased, the resonance frequency will decrease and the charge sensitivity or output charge per acceleration unit applied will increase. Small mass units are capable of a wide range of frequency responses, and large mass units are optimum for measurement of small values of acceleration.
- **Mounted Resonance Frequency** The resonance frequency is directly proportional to the overall stiffness of the system. Consequently, the proper mounting method depends on the measurement objective and goals. As a general rule, the coupling between the sample and the accelerometer should be as stiff as possible to ensure unwanted resonances are avoided.

Additional factors should also be considered. Piezoelectric accelerometers are not immune to extreme environmental conditions, transverse motion, and magnetic field influences just to mention a few parameters that may affect the measurements. The manufacturer's data sheet should be consulted to ensure proper functioning conditions for the accelerometer.

A large variety of vibration measurement systems can be used, but for general purposes typical systems will be discussed. The transduction stage is performed by a piezoelectric sensor. Refer to Table 6 for a

comparison between different types of accelerometers. In this stage, the vibration of the sample is transmitted to the sensor, which converts it to an electrical signal proportional to the acceleration. The electrical signal from the sensor must be conditioned (i.e., amplified and impedance coupled). This is done by a charge-to-voltage converter.

The filtering stage, whose function is to reject undesired information, is done by electrical filtering of the output of the preamplifier. Note that this filtering stage only improves accuracy by omitting irregularities caused by the mechanical properties of the sensor (i.e., resonance frequency) or by simplifying the data gathered. However, to protect the accelerometer against excessive shock that could damage the device, mechanical filters may be needed, especially to protect it in the region near to and at its resonance frequency.

Sometimes the purpose of the measurement is not to determine the acceleration of an object but to measure its velocity or displacement. The integration stage makes this possible by integrating the acceleration. This is now generally done by a digital algorithm, but it can be done by analog integration.

The detection, linear to logarithm conversion, display, and logging are the final stages of the measurement chain. Before the detection phase, the signal processed is still an alternating current. A detector converts it to a direct current signal to produce the rms acceleration reading. Yet, due to the vast range of values, an additional process converts the rms acceleration values to acceleration levels in decibels referenced to 10^{-6} m/s^2 . Then the results are finally displayed. The display can be analog or digital in

form. Several analysis tools are used for displaying the results (e.g., real-time frequency analyzers, printers, etc.). The results can also be recorded for later processing preferably in the digital domain.

Two actual vibration measurements are presented in Figs. 22 and 23. Figure 22 shows a decoupled lifter motor with measurements taken on the motor block and on the concrete inertia base. The decoupling is seen to work well above the strong first resonance at 18 Hz. Figure 23 shows measurements on a new windshield wiper motor undergoing its first 450 runs in a quality control test. The vibration levels generated during each run were measured by an accelerometer and analyzed in $\frac{1}{12}$ th octave bands. It is clear that certain bands show an abrupt change in level during the first 20 runs (63 Hz, 160 Hz, 630 Hz, and 750 Hz). Since each run takes 24 s to complete, these frequency bands were found not to be useful for a pass-fail test for these small motors in which a quick detection of defective components is required.

Acknowledgment The authors would like to thank Antonio Sandoval Martinez for his assistance in the preparation of this chapter.

CHAPTER 44

DETERMINATION OF SOUND POWER LEVEL AND EMISSION SOUND PRESSURE LEVEL

Hans G. Jonasson

SP Technical Research Institute of Sweden
Borås, Sweden

1 DETERMINATION OF SOUND POWER LEVEL USING SOUND PRESSURE

1.1 Introduction

The noise emission from machinery is best described by the sound power level. Contrary to the sound pressure level, the sound power level is in principle independent of the acoustical properties of the room in which the machine is located. The sound power level is also the best quantity to use when calculating the sound pressure level in the reverberant field of the room in which the source is located. In addition to the sound power level, the emission sound pressure level, that is, the sound pressure level in a hemianechoic test environment, is used to describe the noise emission of machinery in the direct field of the source.

In many cases the sound power level will depend strongly on the mounting and operating conditions. In order to be able to compare the noise emission from similar machines from different manufacturers such conditions have to be standardized. This is done in machine-specific test codes (also called C-standards). These C-standards always use one or several of the basic measurement standards (also called B-standards) described in the following. Thus, before carrying out sound power measurements, it is essential to check if there is such a test code for the machine to be tested. In case there is no such test code, it is customary to select one or more of the following operating conditions: full load, no load (idling), conditions corresponding to maximum sound generation, representative operating conditions, or other specified operating conditions. Whichever conditions are used, they must be described carefully in the test report.

1.2 Overview of Available Standards

The sound power level can be determined in many different ways. In principle all methods should give the same result,^{1,2} although with different measurement uncertainties. Some of the methods are based on measurements of sound pressure and some on sound intensity. Here only the International Organization for Standardization (ISO) 3740 series^{3–9} describing methods using sound pressure will be discussed. All these standards are also European standards and equivalent North American standards, and Japanese industrial standards are normally identical. The most suitable method to use in a given case is determined by the desired measurement uncertainty and by the available test environment and test equipment.

Sometimes the machine cannot be moved but must be measured in situ, and sometimes it is most practical to carry out the measurement in a dedicated laboratory.

In the ISO 3740 series the measurement uncertainty is divided into three different classes: grade 1, grade 2, and grade 3, also known as precision, engineering, and survey methods. Grade 1, which is the most accurate method, has a standard deviation of reproducibility less than 1 dB, whereas grade 2 and grade 3 are less than 2 and 3 dB, respectively.

The normal quantity to be measured is the time-averaged sound pressure level (also called equivalent continuous sound pressure level), but sometimes the single-event sound pressure level (also called sound exposure level) is also used. They are defined as

$$L_{p,eq,T} = 10 \log \left[\frac{1}{T} \int_0^T 10^{0.1 L_p(t)} dt \right] \text{ dB} \quad (1)$$

$$\begin{aligned} L_{p,1s} &= 10 \log \left[\frac{1}{T_0} \int_0^T 10^{0.1 L_p(t)} dt \right] \\ &= L_{p,eq,T} + 10 \log \left(\frac{T}{T_0} \right) \text{ dB} \end{aligned} \quad (2)$$

respectively, where T is the time interval for the measurement, T_0 equals 1 s, and $L_p(t)$ the instantaneous sound pressure level. In the ISO 3740 series $L_{p,eq,T}$ is normally simply denoted L_p . Then L_p is used to calculate the sound power level and $L_{p,1s}$ to calculate the sound energy level, L_J . The sound energy level is of particular interest for sources emitting single bursts of sound. It should be observed that nowadays it is recognized that L_J can be determined both in a hemianechoic and in a reverberant environment. If L_p is replaced by $L_{p,1s}$ in the following formulas, L_W can be replaced by L_J .

Sometimes it is required to evaluate the presence of prominent tones. There are no objective methods to determine prominent tones in the basic sound power standards. However, there is one method in the test code ISO 7779¹⁰ for information technology equipment.

A very simple overview of the different standards for determination of sound power levels is given in Table 1. The reproducibility standard deviation is a measure of the measurement uncertainty, see clause 1.6. More detailed guidance is given in ISO 3740.³

Table 1 Selection of Measurement Method

Standard ISO	Measurement Environment	Reproducibility Standard Deviation of the A-weighted Sound Power Level (dB)	Equipment in Addition to Sound Level Meter	Minimum Number of Microphone Positions	Background Noise Tolerance	Subclause
3741	Reverberation room	0.5	Equipment to determine reverberation time or a reference sound source	6	Poor	1.5
3743-1	Room with hard walls with $V \geq 40 \text{ m}^3$	1.5	Reference sound source, octave filter	3	Poor	1.4
3743-2	Special reverberation room with $V \geq 70 \text{ m}^3$	2.0		6	Poor	1.4
3744	Outdoors, large room, hemianechoic room with max environmental correction $K_2 = 2 \text{ dB}$	1.5		9	Good	1.5
3745	Hemianechoic room with maximum environmental correction $K_2 = 0.5 \text{ dB}$	0.5		20	Moderate	1.3
3746	Outdoors, ^a large room with maximum environmental correction $K_2 = 7 \text{ dB}$	3.0		4	Good	1.3
3747	Any indoor environment, which is a little reverberant	1.5	Reference sound source, octave filter	3	Poor	1.4

^aISO 3746 is the only standard that can be used on grass or soft earth.

1.3 Measurement Surface Methods

1.3.1 General The most basic method to determine the sound power level from a machine is to determine the mean sound pressure level on a measurement surface, that is, a hypothetical surface completely enclosing the machine under test and on which the measurement points are located. The sound power level is then given by

$$L_W = \overline{L_{pf}} + 10 \log \left(\frac{S}{S_0} \right) + C_1 \quad (3)$$

where $\overline{L_{pf}}$ = mean sound pressure level on the (measurement surface dB)

S = area of measurement surface (m^2)

$S_0 = 1 \text{ m}^2$

$$C_1 = -10 \log \left(\frac{B \sqrt{T_0}}{B_0 \sqrt{T}} \right) \quad (4)$$

B = static atmospheric pressure during the test

T = temperature, in K

$B_0 = 1013.25 \text{ hPa}$

$T_0 = 313.15 \text{ K}$

Normally, the measurement surface is a box on the floor (= 5 sides) or a hemisphere as the source most often is located on a floor away from all other room boundaries. If the source is located close to a wall, the measurement surface is half a box on the floor (= 4 sides) or a $\frac{1}{4}$ sphere. If the source is located in a corner, the measurement surface is $\frac{1}{4}$ of a box on the floor (= 3 sides) or a $\frac{1}{8}$ sphere, respectively. Whenever the source approaches a boundary surface the sound power output will be affected.¹¹ This effect is not properly taken into account in the ISO 3740 series. However, this effect is normally negligible for all but the lowest frequency bands.

Term C_1 corrects the sound power level to actual meteorological conditions. The meteorological conditions will also affect the radiation from the source.¹² The latter will vary with the acoustic impedance of air, which in its turn varies with the atmospheric pressure and the temperature. To compensate for that, it has been decided to normalize measured sound power levels to the reference barometric pressure B_0 and the temperature 23°C (= 296.15 K). This normalized sound power level, $L_{W,N}$ is given by

$$L_{W,N} = \overline{L_{pf}} + 10 \log \left(\frac{S}{S_0} \right) + C_1 + C_2 \quad (5)$$

where

$$C_2 = -15 \log \left(\frac{BT_1}{B_0T} \right) \quad (6)$$

where $T_1 = 296.15$ K. Up until now both C_1 and C_2 have been neglected in all standards except precision methods ISO 3741 and 3745. It is expected that similar corrections will be introduced in the future also into some other standards.

The mean sound pressure level on the measurement surface is given by

$$\overline{L_{pf}} = 10 \log \left(\frac{1}{n} \sum_{i=1}^n 10^{0.1L_{pi}} \right) \quad (7)$$

where L_{pi} is the sound pressure level in measurement position i on the measurement surface. In ISO 3744 the general principle is that each position must be associated with an equally large area on the measurement surface, and, if the difference between any two positions exceeds the number of positions, the number of positions has to be increased.

Equation (5) presumes that the intensity is measured along the normal to the measurement surface only. This is only obtained with a measurement of intensity, but for a sound pressure measurement it also fits well for a spherical or hemispherical measurement surface at a reasonably long distance. However, if the measurement surface is box shaped at a short distance, the sound will come from many different angles and not only along the normal. In that case L_{pi} will be overestimated^{13,14} and we get a systematical overestimate of the sound power. This overestimate is normally rather small and ignored. However, to improve the reproducibility, it is recommended to use only one shape of reference surface for each type of machine.

Equation (5) is valid when there are no reflections from walls and ceiling. Some standards allow a correction, K_2 , for such reflections, and we then get

$$L_W = \overline{L_{pf}} + 10 \log \left(\frac{S}{S_0} \right) + C_1 + C_2 - K_2 \quad (8)$$

where the environmental correction K_2 is a correction to compensate for the increase in sound pressure level on the measurement surface due to reflections from walls, ceiling, and other reflecting objects in the vicinity, but excluding surfaces within the measurement surface, of the machine under test. Outdoors or in a hemianechoic room $K_2 = 0$ dB. In other cases corrections have to be made. ISO 3744, which has the uncertainty of an engineering method, allows for corrections up to 2 dB, whereas the survey method ISO 3746 allows for corrections up to 7 dB. For ISO 3744 it has been proposed to increase the maximum allowable correction from 2 to 4 dB.

The term K_2 , which describes the increase in sound pressure level on the measurement surface due to the

reverberant sound field in the room, is calculated from

$$K_2 = 10 \log \left(1 + 4 \frac{S}{A} \right) \quad (9)$$

where A is the sound absorption area of the room estimated from:

$$A = \alpha S_v \quad (10)$$

where α is the mean sound absorption coefficient of the room surfaces, which for A-weighted levels can be estimated from tables in the relevant standards; S_v is the total area of the boundary surfaces (walls, ceiling, and floor) of the test room, in meters squared; A can also be determined in frequency bands by measurements, for example, with a reference sound source or from reverberation time.

1.3.2 The Sphere Method The most accurate measurement surface method is the sphere method. In that case the measurement is a sphere or part thereof. At first the smallest possible imaginary box, the *reference box* is constructed, which completely encloses the source to be tested and all its important sound radiating parts. The reference box defines the size of the source with its characteristic distance d_0 , the distance from the projection of the center of the reference box on the floor and one of the upper corners. Then a measurement distance, the radius R , of the hemispherical measurement surface, which is at least twice d_0 is selected. For large sources d_0 becomes large, and it is then often more practical to use a box-shaped measurement surface. The basic measurement positions on the hemispherical measurement surface are located as shown in Fig. 1. The engineering method ISO 3744 normally uses the 10 locations shown in the figure, whereas the survey method ISO 3746 only requires positions 4, 5, 6, and 10. Each position must represent an equally large area. If the largest difference in sound pressure level, in decibels, between any two positions exceeds the number of positions, then the number of positions must be increased. The precision method ISO 3745 requires 20 different positions, each at a different height. If the source under test emits stationary sound, it is also permissible to determine the surface sound pressure level using traversing microphone paths.

1.3.3 The Box Method The simplest and most popular measurement surface method is the box method, see Fig. 2. In this case the measurement surface is box shaped with each of the sides at the preferred measurement distance, $d = 1.0$ m from the reference box. Alternatively, measurement distances shorter or longer than 1.0 m may be selected. Short distances require more microphone positions but improve the signal-to-noise ratio if the background noise is high. The basic microphone positions used in the engineering method ISO 3744 are on the middle of each side and in the four upper corners. More positions

Figure 1 Basic microphone positions on a hemispherical measurement surface according to ISO 3744. The microphone heights are $0.15R$, $0.45R$, $0.75R$, and R , respectively.

are required for large sources. For survey-grade measurements the corner positions can be left out.

1.4 The Comparison Method

The comparison method is accurate, simple, and quick and is particularly suitable when one has no access to dedicated laboratories.¹⁴ The principle is to compare the sound pressure level L_p from the source under test with the sound pressure level L_{pref} from a calibrated reference sound source with the known sound power level L_{Wref} . The unknown sound power level of the source under test is then given by

$$L_W = L_{Wref} + L_p - L_{pref} \quad (11)$$

To be accurate, the measurements have to be made in frequency bands and the A-weighted sound power level is then calculated. The comparison method is standardized in ISO 3743 and 3747 for in situ use. It is also an alternative for reverberation room measurements according to ISO 3741 and to determine the environmental correction K_2 in ISO 3744 and 3746. The reference sound source must meet the requirements of ISO 6926.¹⁵

In ISO 3743-1, which is specifically designed to be used for small movable sources, the test environment must be a hard-walled room; that is, a room without major sound absorbing boundary surfaces, with a minimum volume of 40 m^3 and at least 40 times the volume of the reference box. A sound absorbing surface is a surface with a sound absorption coefficient exceeding 0.20. At least three microphone positions, the same ones for both the source under test and the reference sound source, must be used, and the measurements are carried out in octave bands. The standard deviation of the reproducibility is in general 1.5 dB for the A-weighted sound power level. The method is a substitution method; that is, the source under test is moved and replaced by the reference sound source when the sound pressure generated by the latter is measured.

ISO 3747 is a true in situ method where it is assumed that the source under test is not movable. Normally, the reference sound source is located on top of the source under test. To guarantee grade 2 accuracy (engineering method), the test environment should be a little reverberant. The quality of the test environment is tested by carrying out a measurement of the excess of sound pressure level, DL_f , using the reference sound

Figure 2 Basic microphone positions on a box-shaped measurement surface for a small source.

source. DL_f is given by

$$DL_f = L_{\text{pref}} - L_{W\text{ref}} + 11 + 20 \log \left(\frac{r}{r_0} \right) \quad (12)$$

where r is the distance between the reference sound source and the microphone; $r_0 = 1$ m. To meet the accuracy requirements of a grade 2 method, r of the different microphone positions used must be selected such that $DL_f \geq 7$ dB in each microphone position.

1.5 The Reverberation Method

This method is used in reverberant rooms. In order to meet the requirements for the standard ISO 3741, a special reverberation room has to be used. The most common size for such a room is 200 m³. It is then qualified for the frequency range of 100 to 10,000 Hz. If lower frequencies are of interest, the room should be larger. The measurements are carried out in $\frac{1}{3}$ octave bands. Two methods are allowed. One is the comparison method and the other is the direct method. In the direct method the reverberation time and the mean sound pressure level in the room are measured. The sound power level is then given by

$$L_W = \overline{L_p} + 10 \log \left(\frac{A}{A_0} \right) + 10 \log \left(1 + \frac{Sc}{8Vf} \right) + 4.34 \frac{A}{S} - 6 + C_1 + C_2 \quad (13)$$

where $\overline{L_p}$ = mean sound pressure level in the room (dB)

A = equivalent sound absorption area of the room (m²) determined from the reverberation time

$A_0 = 1$ m²

S = total surface area of the reverberation room (m²)

c = speed of sound at the temperature θ , $c = 20.05 \sqrt{273 + \theta}$ m/s

θ = temperature (°C)

V = volume of the room (m³)

f = center frequency of the one-third octave band used for the measurement (Hz)

The term $10 \log (1 + Sc/8 V/f)$ is a correction to compensate for the fact that the mean sound pressure level is not measured throughout the room volume but at least 1.0 m away from the boundary surfaces. As the energy density always is greatest close to the walls, this leads to a systematic underestimate of the true mean sound pressure level. The term $4.34A/S$ accounts for the air absorption in the room.¹⁶ C_1 and C_2 are the same corrections as for ISO 3745 with the difference that the reference condition for the normalized sound power level is that of $\rho c = 400$ Ns/m³ instead of standard barometric pressure and 23°C. It is recommended not to use this reference

condition of ISO 3741 but to use the reference condition of the most recent standard ISO 3745, that is, $B = B_0$ and $t = 23^\circ\text{C}$, as this condition will be used in future standards:

$$A = \frac{55.26}{c} \left(\frac{V}{T_{\text{rev}}} \right) \quad (14)$$

The reverberation method is the most accurate and most convenient method to use for broadband noise sources provided that a reverberation room is available. The method is not as good for sources emitting narrow-band noise. To discover such problematic cases, ISO 3741 requires the use of six discrete microphone positions. For each measurement the standard deviation of these positions has to be evaluated. If it is too high, there are good reasons to assume that the source emits narrow-band noise, and it is then necessary to change the measurement procedure by using more source and/or microphone positions. There is also an option to avoid these additional positions by qualifying the room for narrow-band measurements by using rotating diffusors. However, this qualification procedure is quite difficult. To decrease the problems with tonal sounds, it is recommended not to have too long reverberation times as the modal overlapping improves with a higher sound absorption. When many microphone positions are required, it may be useful to use a moving microphone instead. The reverberation room method is standardized as a precision method in ISO 3741. The standard deviation of reproducibility of the A-weighted sound power level is 0.5 dB.

A special method in a special reverberation room is described in ISO 3743-2. That method was originally developed to make it possible to measure A-weighted sound pressure levels directly in a reverberant field. To make that possible the reverberation room has to be qualified to have a reverberation time following a specified frequency dependence. The development of modern instrumentation and better comparison methods has made this standard outdated.

1.6 Measurement Uncertainties

Traditionally, the measurement uncertainty in the ISO 3740 series is given in terms of the reproducibility standard deviation, σ_R . If a particular noise source were to be transported to each of a number of different test sites, and if at each test site the sound power level of that source were to be determined in accordance with the respective standard, but with different test personnel and different equipment, the results would show a scatter. Assuming that the variations in noise emission of the source were negligible, the maximum standard deviation of all these sound power level values is σ_R . The measurement uncertainty to be reported is the combined measurement uncertainty associated with a chosen coverage probability. By convention, a coverage probability of 95% is usually chosen, with an associated coverage factor of 2. This means that the result becomes $L_{WA} \pm 2\sigma_R$. The σ_R values of the different methods are given in Table 1.

In the near future, ISO plans to change to the format of ISO Guide to the Expression of Uncertainties in Measurements.¹⁷ When it is implemented, it will be necessary to identify each source of error and the standard uncertainty, u_j , associated with it. Depending on the probability distribution, each error has a sensitivity coefficient c_j . A normal distribution has a sensitivity coefficient of 1. The combined standard uncertainty is then given by

$$u(L_W) = \sqrt{\sum_{j=1}^n (c_j u_j)^2} \quad (15)$$

1.7 Noise Declarations

Many sound power determinations are carried out on behalf of manufacturers who want to or have to declare the noise emission values of their products. For such declarations the measurement uncertainty and the standard deviation of production have to be taken into account. How this can be done is most simply described in ISO 4871¹⁸ and, for computer and business equipment, in ISO 9296.¹⁹ Both these standards are based on the more basic and more complicated standard ISO 7574.²⁰ Sometimes a noise test code may give additional information. ISO 4871 permits noise declarations either as declared single-number noise emission values or as declared dual-number noise emission values.

The declared single-number noise emission value for a production series of machines can be calculated from

$$L_d = \bar{L} + K \quad (16)$$

where \bar{L} is the mean value of a batch of the production, preferably from at least three different machines, and K is the expanded uncertainty. L is normally either the A-weighted sound power level L_{WA} or the A-weighted emission sound pressure level L_{pA} , but also other acoustical quantities can be declared accordingly. The value of K , in decibels, for a sample size of three machines is

$$K = 1.5s_t + 0.564(\sigma_M - s_t) \quad (17)$$

where the total standard deviation s_t is given by

$$s_t = \sqrt{s_R^2 + s_P^2} \quad (18)$$

Here s_P is the standard deviation of the production and s_R the standard deviation of the reproducibility. Values of s_t and σ_M may be given in the test code, but, if there is no such code available, the values given in Table 2 may be used. Only L_d is reported.

The declared single-number noise emission value is also called guaranteed value. The value of K determined above is based on ISO 7574-4 and results in a 5% risk of rejection for a sample of three machines. If a single machine out of batch is evaluated,

Table 2 Estimated Default Values for s_t and σ_M

Accuracy Grade of Measurement Method	Estimated Values (dB)	
	s_t	σ_M
Engineering (grade 2)	2.0	2.5
Survey (grade 3)	3.5	4.0

the declared value is verified if the measured value is equal to or less than the declared value. A batch is verified if the mean value of three tested machines is at least 1.5 dB lower than the declared value. A dual-number declaration means that the measured value \bar{L} and the uncertainty K both are reported.

2 DETERMINATION OF EMISSION SOUND PRESSURE LEVEL

2.1 Introduction

The emission sound pressure level is defined as the sound pressure level in a specified location, the operator's position, if there is one, from a machine under standardized operating conditions in a test environment where the influence from all boundary surfaces, but the floor is negligible. It is best measured in a hemianechoic room.

In the ISO 11200 series^{21–26} five different standards to determine the emission sound pressure level are described. One of the standards, ISO 11205,²⁶ uses the sound intensity level to approximate the emission sound pressure level. The quantities normally measured are L_{pAeq} , $L_{pA,1s}$ and L_{pCpeak} . A standing operator or bystander is specified to be located at the height $1.55 \text{ m} \pm 0.075 \text{ m}$ above the floor. If there is a seat, the microphone must be located $0.8 \pm 0.05 \text{ m}$ above the middle of the seat plane. If an operator is present, the microphone must be $0.20 \pm 0.02 \text{ m}$ to the side of the center plane of the operator's head.

2.2 Laboratory Methods

The most common laboratory method for the determination of emission sound pressure level is ISO 11201.²² This standard requires the same environment as ISO 3744,⁶ which means that the environmental correction, K_2 , at the measurement position may be up to 2 dB. However, contrary to ISO 3744 the standard does not allow any corrections. The measured value, corrected for background noise if relevant, is always the result. This is very unfortunate as this in principle means that room-dependent errors up to about 2 dB are accepted. Fortunately, most laboratories use hemianechoic rooms qualified according to ISO 3745,⁷ which means that $K_2 \leq 0.5 \text{ dB}$. The operating conditions must be the same as those for the determination of sound power levels. Operating conditions are generally defined in machine-specific test codes.

In case there is no dedicated workplace, one either measures in the bystander positions in the middle of each side, 1 m from the sides of the reference box, or applies ISO 11203.²⁴ This standard calculates the

emission sound pressure level from the sound power level using the equation:

$$L_p = L_W - 10 \log \left(\frac{S}{S_0} \right) \quad (19)$$

where S is the box-shaped measurement surface on which the specified position is located. If there is no specified position, the distance is 1.0 m from the reference box. S_0 is 1 m^2 .

2.3 In Situ Methods

For general field use ISO 11202²³ is the best method. Here the emission sound pressure level is given by

$$L_p = L'_p - K_3 \quad (20)$$

where L'_p is the measured sound pressure level, and the local environmental correction K_3 is given by

$$K_3 = 10 \log \left(1 + 4 \frac{S}{A} \right) \quad (21)$$

where $S = 2\pi a^2$, where a is the distance from the measurement point to the closest important sound source on the machine; A is the equivalent sound absorption area of the test room, which is estimated as prescribed in ISO 3746 for sound power measurements. In the present standard K_3 is not allowed to be greater than 2.5 dB. However, investigations²⁷ have shown that more accurate results are achieved if K_3 values up to 4 dB are allowed.

If a lower measurement uncertainty is desirable ISO 11204²⁵ can be applied. In that case either the sound power level has to be known or the sound pressure level has to be measured in several positions around the machine. The problem with this standard is that it is not always applicable. ISO 11205²⁶ is an interesting alternative in cases where the machine is located in a very reverberant environment.²⁸ In that case the sound intensity level is measured in the three Cartesian directions x , y , and z . The emission sound pressure level L_p is given by

$$L_p = L_{Ixyz} + K_5 \quad (22)$$

where $K_5 = 1 \text{ dB}$ and

$$L_{Ixyz} = 10 \log \sqrt{\left(10^{\frac{L_{Ix}}{10}} \right)^2 + \left(10^{\frac{L_{Iy}}{10}} \right)^2 + \left(10^{\frac{L_{Iz}}{10}} \right)^2} \quad (23)$$

where L_{Ix} , L_{Iy} , and L_{Iz} are the sound intensity levels determined in the three Cartesian directions.

When measuring $L_{pC\text{peak}}$ for impulsive sound sources reflections^{29,30} from the boundary surfaces have less effect than is the case for L_p . Thus, no corrections are allowed for $L_{pC\text{peak}}$. Peak values are

normally measured 10 times and the measurement result is the highest value.

CHAPTER 45

SOUND INTENSITY MEASUREMENTS

Finn Jacobsen
Acoustic Technology
Technical University of Denmark
Lyngby, Denmark

1 INTRODUCTION

Sound intensity is a measure of the flow of energy in a sound field. Sound intensity measurements make it possible to determine the sound power of sources without the use of costly special facilities such as anechoic and reverberation rooms. Other important applications of sound intensity include the identification and rank ordering of partial noise sources, visualization of sound fields, determination of the transmission losses of partitions, and determination of the radiation efficiencies of vibrating surfaces.

Measurement of sound intensity involves determining the sound pressure and the particle velocity at the same position simultaneously. The most common method employs two closely spaced pressure microphones and is based on determining the particle velocity using a finite difference approximation of the pressure gradient.

The sound intensity method is not without problems, and more knowledge is required in measuring sound intensity than in, say, using an ordinary sound level meter. The difficulties are mainly due to the fact that the accuracy of sound intensity measurements with a given measurement system depends very much on the sound field under study. Another problem is that the distribution of the sound intensity in the near field of a complex source is far more complicated than the distribution of the sound pressure, indicating that sound fields can be much more complicated than earlier realized.

2 SOUND FIELDS, SOUND ENERGY, AND SOUND INTENSITY

2.1 Fundamental Relations

The instantaneous sound intensity $\mathbf{I}(t)$ is a vector that describes the rate and direction of the net flow of sound energy per unit area as a function of time t . The dimensions of this quantity are energy per unit time per unit area (W/m^2). The instantaneous sound intensity equals the product of the sound pressure $p(t)$ and the particle velocity $\mathbf{u}(t)$,¹

$$\mathbf{I}(t) = p(t)\mathbf{u}(t) \quad (1)$$

By combining some of the fundamental equations that govern a sound field, the equation of conservation of mass, the adiabatic relation between changes in the sound pressure and in the density, and Euler's equation

of motion, one can derive the equation

$$\int_S \mathbf{I}(t) \cdot d\mathbf{S} = -\frac{\partial}{\partial t} \left(\int_V w(t) dV \right) = -\frac{\partial E(t)}{\partial t} \quad (2)$$

in which $w(t)$ is the instantaneous total sound energy density, S is the area of a closed surface, V is the volume enclosed by the surface, and $E(t)$ is instantaneous total sound energy within the surface.² The left-hand term is the net outflow of sound energy through the surface, and the right-hand term is the rate of change of the total sound energy within the surface. This is the equation of conservation of sound energy, which expresses the simple fact that the net flow of sound energy out of a closed surface equals the (negative) rate of change of the sound energy within the surface because the energy is conserved.

In practice, we are usually concerned with the time-averaged sound intensity in stationary sound fields:

$$\langle \mathbf{I}(t) \rangle_t = \langle p(t)\mathbf{u}(t) \rangle_t \quad (3)$$

For simplicity we use the symbol \mathbf{I} for this quantity rather than the more precise notation $\langle \mathbf{I}(t) \rangle_t$. If the sound field is harmonic with angular frequency $\omega = 2\pi f$, we can make use of the usual complex representation of the sound pressure and the particle velocity, which leads to the expression

$$\mathbf{I} = \frac{1}{2} \text{Re}\{p\mathbf{u}^*\} \quad (4)$$

where \mathbf{u}^* denotes the complex conjugate of \mathbf{u} .

It is possible to show from Eq. (2) that the integral of the time-averaged intensity over a surface that encloses a source equals the sound power emitted by the source P_a , that is,

$$\int_S \mathbf{I} \cdot d\mathbf{S} = P_a \quad (5)$$

irrespective of the presence of steady sources outside the surface.^{1,2} This important equation is the basis of sound power determination using sound intensity. Another consequence of Eq. (2) is that the integral is zero:

$$\int_S \mathbf{I} \cdot d\mathbf{S} = 0 \quad (6)$$

when there is neither generation nor dissipation of sound energy within the surface, irrespective of the presence of steady sources outside the surface.

In a plane wave propagating in the r direction the sound pressure p and the particle velocity u_r are in phase and related by the characteristic impedance of air, ρc , where ρ is the density of air and c is the speed of sound:

$$u_r(t) = \frac{p(t)}{\rho c} \quad (7)$$

Under such conditions the intensity is

$$\begin{aligned} I_r &= \langle p(t)u_r(t) \rangle_t = \langle p^2(t) \rangle_t \\ \rho c &= p_{\text{rms}}^2 \\ \rho c &= \frac{|p|^2}{2\rho c} \end{aligned} \quad (8)$$

where p_{rms}^2 is the mean square pressure and p in the rightmost expression is the complex amplitude of the pressure in a plane wave in which the sound pressure is a sinusoidal function of time. In the particular case of a plane propagating wave, the sound intensity is seen to be simply related to the mean square sound pressure, which can be measured with a single microphone. Equation (8) is also valid in the important case of a simple spherical sound field generated by a monopole source under free-field conditions, irrespective of the distance to the source. A practical consequence of Eq. (8) is the following extremely simple relation between the sound intensity level (relative to $I_{\text{ref}} = 1 \text{ pW/m}^2$) and the sound pressure level (relative to $p_{\text{ref}} = 20 \text{ }\mu\text{Pa}$):

$$L_I \simeq L_p. \quad (9)$$

This is due to the fact that

$$\rho c \simeq \frac{p_{\text{ref}}^2}{I_{\text{ref}}} = 400 \text{ kg} \cdot \text{m}^{-2} \cdot \text{s}^{-1} \quad (10)$$

in air under normal ambient conditions. At a static pressure of 101.3 kPa and a temperature of 23°C, the error is about 0.1 dB.

However, in the general case the sound intensity is *not* simply related to the sound pressure, and both the sound pressure and the particle velocity must be measured simultaneously, and their instantaneous product time averaged as indicated by Eq. (3). This requires the use of a more complicated device than a single microphone. The sound intensity level is usually, although not always, lower than the sound pressure level.³

2.2 Active and Reactive Sound Fields

In spite of the diversity of sound fields encountered in practice, some typical sound field characteristics can be identified. For example, the sound field far

from a source under free-field conditions has certain well-known properties, the sound field near a source has other characteristics, and some characteristics are typical of a reverberant sound field.

It was mentioned above that the sound pressure and the particle velocity are in phase in a plane propagating wave. This is also the case in a free field, sufficiently far from the source that generates the field. Conversely, one of the characteristics of the sound field near a source is that the sound pressure and the particle velocity are partly out of phase. To describe such phenomena one may introduce the concept of active and reactive sound fields.

In a harmonic sound field the particle velocity may, without loss of generality, be divided into two components: one component in phase with the sound pressure and one component 90° out of phase with the sound pressure.⁴ The instantaneous *active* intensity is the product of the sound pressure and the in-phase component of the particle velocity. This quantity has a nonzero time average: the time-averaged sound intensity, usually simply referred to as the sound intensity. The instantaneous *reactive* intensity is the product of the sound pressure and the out-of-phase component of the particle velocity. This quantity has a time average of zero, indicating that the sound energy is moving back and forth in the sound field without any net flow.

Very near a sound source the reactive field is usually stronger than the active field. However, the reactive field dies out rapidly with increasing distance to the source, and, even at a fairly moderate distance from the source, the sound field is dominated by the active field. The extent of the reactive field depends on the frequency, the dimensions, and the radiation characteristics of the sound source. In practice, the reactive field may usually be assumed to be negligible at a distance greater than, say, half a metre from the source.

Figures 1, 2, and 3 demonstrate the physical significance of the active and reactive intensities. Figure 1 shows the result of a measurement at a position about 30 cm (about one wavelength) from a small monopole source, an enclosed loudspeaker driven with a band of one-third octave noise. The sound pressure and the particle velocity (multiplied by ρc) are almost identical; therefore the instantaneous intensity is always positive: This is an *active* sound field. In Fig. 2 is shown the result of a similar measurement very near the loudspeaker (less than one tenth of a wavelength from the loudspeaker cone). In this case the sound pressure and the particle velocity are almost 90° out of phase, and as a result the instantaneous intensity fluctuates about zero, that is, sound energy flows back and forth, out of and into the loudspeaker. This is an example of a strongly *reactive* sound field. Finally Fig. 3 shows the result of a measurement in a reverberant room several metres from the loudspeaker generating the sound field. Here the sound pressure and the particle velocity appear to be uncorrelated signals. This is neither an active nor a reactive sound field; this is a *diffuse* sound field.

3 MEASUREMENT OF SOUND INTENSITY

Although acousticians have attempted to measure sound intensity since the 1930s, the first reliable measurements did not occur until the middle of the 1970s. Commercial sound intensity measurement systems came on the market in the beginning of the 1980s, and the first international standards for measurements using sound intensity and for instruments for such measurements were issued in the middle of the 1990s. A description of the history of the development of sound intensity measurement is given in Fahy's monograph *Sound Intensity*.¹

The 50-year delay from when Olson submitted his application for a patent for an intensity meter in 1931 to when commercial measurement systems came on the

market in the beginning of the 1980s can be explained by the fact that it is far more difficult to measure sound intensity than to measure sound pressure. The problems are reflected in the extensive literature on the errors and limitations of sound intensity measurement and in the fairly complicated international and national standards for sound power determination using sound intensity, ISO 9614-1, ISO 9614-2, ISO 9614-3, and ANSI S12.12.⁶⁻⁹

Attempts to develop sound intensity probes based on the combination of a pressure transducer and a particle velocity transducer have occasionally been described in the literature, but this method has been hampered by the absence of reliable particle velocity transducers. However, a micromachined transducer called the Microflown has recently become available

Figure 2 Measurement in a reactive sound field. Key as in Fig. 1. One-third octave noise with a center frequency of 250 Hz. (From Ref. 5. Reprinted with permission by Elsevier.)

for measurement of the particle velocity, and a “low-cost intensity probe” based on this device is now in commercial production.¹⁰ Recent results seem to indicate that it has potential.¹¹ However, one problem with any particle velocity transducer, irrespective of the measurement principle, is the strong influence of airflow. Another unresolved problem is how to determine the phase correction needed when two fundamentally different transducers are combined.

Apart from the Microflown intensity probe, all sound intensity measurement systems in commercial production today are based on the “two-microphone”

(or p - p) principle, which makes use of two closely spaced pressure microphones and relies on a finite difference approximation to the sound pressure gradient, and both the IEC 1043 standard on instruments for the measurement of sound intensity¹² and the corresponding North American ANSI standard¹³ deal exclusively with the p - p measurement principle. Therefore, all the considerations in this chapter concern this measurement principle.

Two pressure microphones are placed close to each other. The particle velocity component in the direction of the axis through the two microphones, r , is obtained through Euler’s equation of motion (Newton’s second

Figure 3 Measurement in a diffuse sound field. Key as in Fig. 1. One-third octave noise with a center frequency of 500 Hz. (From Ref. 5. Reprinted with permission by Elsevier.)

law for a fluid):

$$\frac{\partial p(t)}{\partial r} + \rho \frac{\partial u_r(t)}{\partial t} = 0 \quad (11)$$

as

$$\hat{u}_r(t) = -\frac{1}{\rho} \int_{-\infty}^t \frac{p_2(\tau) - p_1(\tau)}{\Delta r} d\tau \quad (12)$$

where p_1 and p_2 are the signals from the two microphones, Δr is the microphone separation distance, and τ is a dummy time variable. The caret indicates the finite difference estimate, which of course is an approximation to the real particle velocity. The sound

pressure at the center of the probe is estimated as

$$\hat{p}(t) = \frac{p_1(t) + p_2(t)}{2} \quad (13)$$

and the time-averaged intensity component in the r direction is

$$\hat{I}_r = \langle \hat{p}(t) \hat{u}_r(t) \rangle_t = \left\langle \frac{p_1(t) + p_2(t)}{2} \times \int_{-\infty}^t \frac{p_1(\tau) - p_2(\tau)}{\rho \Delta r} d\tau \right\rangle_t \quad (14)$$

Some sound intensity analyzers use Eq. (14) to measure the intensity in frequency bands (usually one-third octave bands). Another type calculates the intensity from the imaginary part of the cross spectrum of the two microphone signals, $S_{12}(\omega)$,

$$\hat{I}_r(\omega) = -\frac{1}{\omega \rho \Delta r} \text{Im}\{S_{12}(\omega)\} \quad (15)$$

The time-domain formulation is equivalent to the frequency-domain formulation, and in principle Eq. (14) gives exactly the same result as Eq. (15) when the intensity spectrum is integrated over the frequency band of concern. The frequency-domain formulation, which makes it possible to determine sound intensity with a dual-channel fast Fourier transform (FFT) analyzer, was derived independently by Fahy and Chung in the late 1970s.^{14,15}

The most common microphone arrangements are known as face-to-face and side-by-side microphones. The latter arrangement has the advantage that the diaphragms of the microphones can be placed very near a radiating surface but has the disadvantage that the microphones disturb each other acoustically. At high frequencies the face-to-face configuration with a solid spacer between the microphones is superior.^{16,17} A sound intensity probe produced by Brüel & Kjær is shown in Fig. 4. The “spacer” between the microphones tends to stabilize the “acoustical distance” between them.¹⁶

Figure 4 Sound intensity probe with the microphones in the “face-to-face” arrangement manufactured by Brüel & Kjær. (Courtesy Brüel & Kjær.)

4 ERRORS AND LIMITATIONS IN MEASUREMENT OF SOUND INTENSITY

There are many sources of error in the measurement of sound intensity, and a considerable part of the sound intensity literature has been concerned with identifying and studying such errors. Some of the sources of error are fundamental, and others are associated with various technical deficiencies. One complication is that the accuracy depends very much on the sound field under study; under certain conditions even minute imperfections in the measuring equipment will have a significant influence. Another complication is that small local errors are sometimes amplified into large global errors when the intensity is integrated over a closed surface.¹⁸

The following is an overview of some of the most serious sources of error in the measurement of sound intensity. Those who make sound intensity measurements should know about the limitations imposed by

- The finite difference error¹⁹
- Errors due to scattering and diffraction¹⁷
- Instrumentation phase mismatch²⁰

Other possible errors include

- Additive “false” low-frequency intensity signals caused by turbulent airflow²¹
- A random error caused by electrical noise in the microphones²²

The latter is a problem only at fairly low sound pressure levels (say, below 40 dB relative to 20 μ Pa) and only at low frequencies (say, below 200 Hz).

4.1 High-Frequency Limitations

The most fundamental limitation of the p - p measurement principle is due to the fact that the sound pressure gradient is approximated by a finite difference of pressures at two discrete points. This obviously imposes an upper frequency limit that is inversely proportional to the distance between the microphones; see Fig. 5.

Figure 5 Illustration of the error due to the finite difference approximation. (a) Good approximation at a low frequency and (b) poor approximation at a high frequency. (After Waser and Crocker.²³)

Figure 6 Finite difference error of an ideal two-microphone sound intensity probe in a plane wave of axial incidence for different values of the separation distance: solid line, 5 mm; short dashed line, 8.5 mm; dotted line, 12 mm; long dashed line, 20 mm; dash-dotted line, 50 mm.

In the general case the finite difference error, that is, the ratio of the measured intensity \hat{I}_r to the true intensity I_r , depends on the sound field in a complicated manner.¹⁹ In a plane sound wave of axial incidence the error can be shown to be¹⁶

$$\frac{\hat{I}_r}{I_r} = \frac{\sin k \Delta r}{k \Delta r} \quad (16)$$

where $k = \omega/c$ is the wavenumber. This relation is shown in Fig. 6 for different values of the microphone separation distance. The upper frequency limit of intensity probes has generally been considered to be the frequency at which this error is acceptably small. With 12 mm between the microphones (a typical value) this gives an upper limiting frequency of about 5 kHz.

Equation (16) holds for an ideal sound intensity probe that does not in any way disturb the sound field. This is a good approximation if the microphones are small compared with the wavelength and the distance between them, but it is not a good approximation for a typical sound intensity probe such as the one shown in Fig. 4. The high-frequency performance of a real, physical probe is a combination of the finite difference error and the effect of the probe itself on the sound field. In the particular case of the face-to-face configuration, the two errors tend to cancel each other if the length of the spacer between the microphones equals their diameter; see Fig. 7. The physical explanation is that the resonance of the cavities in front of the microphones gives rise to a pressure increase that to some extent compensates for the finite difference error.¹⁷ Thus, the resulting upper frequency limit of a sound intensity probe composed of half-inch microphones separated by a 12-mm spacer is 10 kHz, which is an octave above the limit determined by the finite difference error when the interference of the microphones on the sound field is ignored; compare Figs. 6 and 7. No similar canceling of errors occurs with the side-by-side configuration.

Figure 7 Error of a sound intensity probe with half-inch microphones in the face-to-face configuration in a plane wave of axial incidence for different spacer lengths: solid line, 5 mm; short longdashed, 8.5 mm; dotted line, 12 mm; long dashed line, 20 mm; dash-dotted line, 50 mm.

4.2 Instrumentation Phase Mismatch

Phase mismatch between the two measurement channels is the most serious source of error in the measurement of sound intensity, even with the best equipment that is available today. It can be shown that the estimated intensity, subject to a phase error φ_e , to a very good approximation can be written as

$$\hat{I}_r = I_r - \frac{\varphi_e}{k \Delta r} \frac{p_{\text{rms}}^2}{\rho c} \quad (17)$$

that is, phase mismatch in a given frequency band gives rise to a bias error in the measured intensity that is proportional to the phase error and to the mean square pressure and inversely proportional to the frequency and to the microphone separation distance.²⁰ In practice one must, even with state-of-the-art equipment, allow for phase errors ranging from about 0.05° at 100 Hz to 2° at 10 kHz. Both the physical phase difference in the sound field and the phase error between the microphones tend to increase with the frequency, from which it follows that this source of error is a potential problem in the entire frequency range—not just at low frequencies as often thought. Both the International Electrotechnical Commission (IEC) standard¹² and the North American ANSI National Standards Institute (ANSI) standard¹³ on instruments for the measurement of sound intensity specify performance evaluation tests that ensure that the phase error is within certain limits.

Equation (17) is often written in the form

$$\hat{I}_r = I_r + \left(\frac{I_0}{p_0^2} \right) p_{\text{rms}}^2 = I_r \left(1 + \frac{I_0}{p_0^2} \frac{p_{\text{rms}}^2}{I_r} \right) \quad (18)$$

where the *residual intensity* I_0 and the corresponding sound pressure p_0 ,

$$\frac{I_0}{p_0^2/\rho c} = -\frac{\varphi_e}{k\Delta r} \quad (19)$$

have been introduced. The residual intensity, which should be measured, for example, in one-third octave bands, is the “false” sound intensity indicated by the instrument when the two microphones are exposed to the same pressure p_0 , for instance, in a small cavity. Under such conditions the true intensity is zero, and the indicated intensity I_0 should obviously be as small as possible. The right-hand side of Eq. (18) demonstrates how the error caused by phase mismatch depends on the ratio of the mean square pressure to the intensity in the sound field—in other words on the sound field conditions.

Phase mismatch of sound intensity probes is usually described in terms of the so-called pressure-residual intensity index:

$$\delta_{pI_0} = 10 \log \left(\frac{p_0^2/\rho c}{I_0} \right) \quad (20)$$

which is just a convenient way of measuring and describing the phase error. With a microphone separation distance of 12 mm, the typical phase error mentioned above corresponds to a pressure-residual intensity index of 18 dB in most of the frequency range. The error due to phase mismatch is small provided that

$$\delta_{pI} \ll \delta_{pI_0} \quad (21)$$

where

$$\delta_{pI} = 10 \log \left(\frac{p_{\text{rms}}^2/\rho c}{I_r} \right) \simeq L_p - L_I \quad (22)$$

is the pressure-intensity index of the measurement. The inequality (21) is simply a convenient way of expressing that the phase error of the equipment should be much smaller than the phase angle between the two sound pressure signals in the sound field if measurement errors should be avoided. A more specific requirement can be expressed in the form⁷

$$\delta_{pI} < L_d = \delta_{pI_0} - K \quad (23)$$

where the quantity

$$L_d = \delta_{pI_0} - K \quad (24)$$

is called the *dynamic capability index* of the instrument and K is the *bias error index*. The dynamic capability index indicates the maximum acceptable value of the pressure-intensity index of the measurement for a given grade of accuracy. The larger the value of K the smaller is the dynamic capability index, the stronger and more restrictive is the requirement, and the smaller

is the error. The condition expressed by the inequality (23) and a bias error index of 7 dB guarantee that the error due to phase mismatch is less than 1 dB, which is adequate for most purposes. This corresponds to the phase error of the equipment being five times less than the actual phase angle in the sound field.

Most engineering applications of sound intensity measurements involve integrating the normal component of the intensity over a surface. The global version of Eq. (18) has the form²⁰

$$\hat{P}_a = P_a \left[1 + \frac{I_0 \rho c}{p_0^2} \frac{\int_S (p_{\text{rms}}^2/\rho c) dS}{\int_S \mathbf{I} \cdot d\mathbf{S}} \right] \quad (25)$$

which shows that the global version of the inequality (23) can be written as

$$\Delta_{pI} < L_d = \delta_{pI_0} - K \quad (26)$$

where

$$\Delta_{pI} = 10 \log \left[\frac{\int_S (p_{\text{rms}}^2/\rho c) dS}{\int_S \mathbf{I} \cdot d\mathbf{S}} \right] \quad (27)$$

is the global pressure-intensity index of the measurement. This quantity plays the same role in sound power estimation as the pressure-intensity index does in measurements at discrete points.

Figure 8 shows examples of the global pressure-intensity index measured under various conditions. It is obvious that the presence of noise sources outside the measurement surface increases the mean square pressure on the surface, and thus the influence of a given phase error; therefore a phase error, no matter how small, limits the range of measurement.

Figure 8 The global pressure-intensity index Δ_{pI} determined under three different conditions: solid line, measurement using a “reasonable” surface; dashed line, measurement using an eccentric surface; and dash-dotted line, measurement with strong background noise. (After Jacobsen.³)

In practice, one should examine whether the inequality (26) is satisfied or not when there is significant noise from extraneous sources. If the inequality is not satisfied, it can be recommended to use a measurement surface somewhat closer to the source than advisable in more favorable circumstances. It may also be necessary to modify the measurement conditions—to shield the measurement surface from strong extraneous sources, for example, or to increase the sound absorption in the room. All modern sound intensity analyzers can determine the pressure-intensity index concurrently with the actual measurement, so one can easily check whether phase mismatch is a problem or not. Some instruments automatically examine whether inequality (26) [or (23) in a point measurement] is satisfied or not and give warnings when this is not the case. It may well be impossible to satisfy the inequality in a frequency band with very little energy; this is, of course, of no concern.

5 CALIBRATION OF SOUND INTENSITY PROBES

The purpose of the IEC standard for sound intensity instruments¹² and its North American counterpart¹³ is to ensure that the intensity measurement system is accurate. Thus, minimum values of the acceptable pressure-residual intensity index are specified for the probe as well as for the processor, and according to the results of a test the instruments are classified as

being of “class 1” or “class 2.” The test involves subjecting the two microphones of the probe to identical pressures in a small cavity driven with wideband noise. As described in Section 4.2, the indicated pressure-intensity index equals the pressure-residual intensity index, which describes how well the two microphones are matched. A similar test of the processor involves feeding the same signal to the two channels.

The pressure and intensity response of the probe should also be tested in a plane propagating wave as a function of the frequency, and the probe’s directional response is required to follow the ideal cosine law within a specified tolerance.

A special test is required in the frequency range below 400 Hz. According to this test the intensity probe should be exposed to the sound field in a standing-wave tube with a specified standing-wave ratio (24 dB for probes of class 1). When the sound intensity probe is drawn through this interference field, the sound intensity indicated by the measurement system should be within a certain tolerance.

Figure 9a illustrates how the sound pressure, the particle velocity, and the sound intensity vary with position in a one-dimensional interference field with a standing-wave ratio of 24 dB. It is apparent that the pressure-intensity index varies strongly with the position in such a sound field. Accordingly, the influence of a given phase error depends on the position, as shown in Fig. 9b. However, the test will

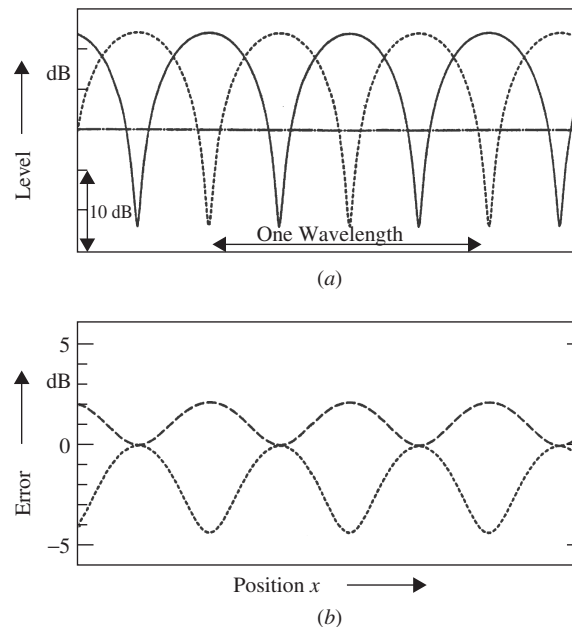

Figure 9 (a) Sound pressure level (solid line), particle velocity level (dashed line), and sound intensity level (dash-dotted line) in a standing wave with a standing-wave ratio of 24 dB. (b) Estimation error of a sound intensity measurement system with a residual pressure-intensity index of 14 dB (positive and negative phase error). (From Ref. 24. Reprinted with permission by Elsevier.⁴)

Figure 10 Response of a sound intensity probe exposed to a standing wave: sound pressure, particle velocity, intensity, and phase-corrected intensity. (After Frederiksen.²⁵)

also reveal other sources of error than phase mismatch, for example, the influence of an unacceptably high vent sensitivity of the microphones.^{24,25}

Figure 10 shows the measured pressure, particle velocity, intensity, and phase-corrected intensity in a standing-wave tube. The phase mismatch has been corrected by measuring the pressure-residual intensity index and subtracting the error term from the biased estimate given by Eq. (18). The remaining bias error is due to nonnegligible vent sensitivity of the particular microphones used in this test.²⁵ Note that the maximum error of the phase-corrected intensity does not occur at pressure maxima in the standing-wave field.

6 APPLICATIONS

Some of the most common practical applications of sound intensity measurements are now briefly discussed.

6.1 Sound Power Determination

One of the most important applications of sound intensity measurements is the determination of the sound power of operating machinery in situ. Sound power determination using intensity measurements is based on Eq. (5), which shows that the sound power of a source is given by the integral of the normal component of the intensity over a surface that encloses the source, also in the presence of other sources outside the measurement surface. Neither an anechoic nor a reverberation room is required. The analysis of errors and limitations presented in Section 4 leads to the conclusion that the sound intensity method is suitable in the following instance:

- For stationary sources in stationary background noise provided that the global pressure-intensity index is within the dynamic capability of the equipment

The method is *not* suitable in the following instances:

- For sources that operate in long cycles (because the sound field will change during the measurement)
- In nonstationary background noise (for the same reason)
- For weak sources of low-frequency noise (because of large random errors caused by electrical noise in the microphone signals)²²

The surface integral can be approximated either by sampling at discrete points or by scanning manually or with a robot over the surface. With the scanning approach, the intensity probe is moved continuously over the measurement surface in such a way that the axis of the probe is always perpendicular to the measurement surface. A typical scanning path is shown in Fig. 11. The scanning procedure, which was introduced in the late 1970s on a purely empirical basis, was regarded with much skepticism for more than a decade²⁷ but is now generally considered to be more accurate and much faster and more convenient than the procedure based on fixed points.^{28,29} A moderate scanning rate, say 0.5 m/s, and a “reasonable” scan line density should be used, say 5 cm between adjacent lines if the surface is very close to the source, 20 cm if it is further away. One cannot use the scanning

Figure 11 Typical scanning path. (After Tachibana.²⁶)

Figure 12 Measurement surface divided into segments. (After Brüel & Kjær.³⁰)

method if the source is operating in cycles; both the source under test and possible extraneous noise sources must be perfectly stationary. The procedure using fixed positions is used when the scanning method cannot be used, for example, because people are not allowed near an engine at full load.

Usually the measurement surface is divided into a number of segments, each of which will be convenient to scan; Fig. 12 shows a simple example. One will often determine the pressure-intensity index of each segment, and the accuracy of each partial sound power estimate depends on whether inequality (23) is satisfied or not, but it follows from inequality (26) that it is the global pressure-intensity index associated with the entire measurement surface that determines the accuracy of the estimate of the (total) radiated sound power. It may be impossible to satisfy inequality (23) on a certain segment, for example, because the net sound power passing through the segment takes a very small value because of extraneous noise; but, if the global criterion is satisfied, then the total sound power estimate will nevertheless be accurate.

Very near a large, complex source the sound field is often very complicated and may well involve regions with negative intensity, and far from a source background noise will usually be a problem, indicating the existence of an optimum measurement surface that minimizes measurement errors.³¹ In practice, one uses a surface of a simple shape at some distance, say 25 to 50 cm, from the source. If there is a strong reverberant field or significant ambient noise from other sources, the measurement surface should be chosen to be somewhat closer to the source under study.

The three International Organization for Standardization (ISO) standards for sound power determination using intensity measurement⁶⁻⁸ have been designed

Figure 13 Distribution of normal intensity over a window transmitting in the 2-kHz one-third octave band. (After Tachibana.³³)

for sources of noise in their normal operating conditions, which may be very unfavorable. In order to ensure accurate results under such general conditions, the user must determine a number of “indicators” and check whether various conditions are satisfied. The most important indicator is the global pressure-intensity index [Eq. (27)], and the most important condition is inequality (26). The standards also specify corrective actions when the requirements fail to be met. In addition ISO 9614-2 specifies a reproducibility test; each segment should be scanned twice with orthogonally oriented patterns, and the difference should be less than a specified value. Fahy, who was the convener of the working group that developed ISO 9614-1 and 9614-2, has described the rationale, background, and principles of the procedures specified in these standards.³² The approach in the corresponding ANSI standard is quite different.⁹ In this standard no less than 26 indicators are described, but it is optional to determine these quantities, and it is left to the user to interpret the data and decide what to do.

6.2 Noise Source Identification and Visualization of Sound Fields

This is another important application of the sound intensity method. A noise reduction project usually starts with the identification and ranking of noise sources and transmission paths, and sound intensity measurements make it possible to determine the partial sound power contribution of the various components

directly. Plots of the sound intensity normal to a measurement surface can be used in locating noise sources. Figure 13 shows an example of a plot of the normal intensity over a window transmitting sound. The dominant radiation of sound near edges and corners is clearly seen.

Visualization of sound fields, helped by modern computer graphics, contributes to our understanding of the sound radiation of complicated sources. Figure 14 shows vector plots near a seismic vibrator, and Fig. 15

shows the results of similar measurements near a musical instrument (a recorder).

6.3 Radiation Efficiency of Structures

The radiation efficiency of a structure is a measure of how effectively it radiates sound. This dimensionless quantity is defined as

$$\sigma = \frac{P_a}{\rho c \langle v_n^2 \rangle S} \quad (28)$$

Figure 14 Sound intensity vectors in the 80-Hz one-third octave band measured near a seismic vibrator. Components in (a) the x-y plane and (b) the y-z plane. (From Ref. 34. Reprinted with permission by Elsevier.)

Figure 15 Sound intensity distribution in the sound field generated by a recorder. (a) Fundamental (520 Hz) and (b) second harmonic (1040 Hz). (After Tachibana.³⁵)

where P_a is the sound power radiated by the structure of surface area S , v_n is normal velocity of the surface, and the angular brackets indicate averaging over time as well as space. The sound intensity method is

suitable for measuring the radiated sound power. In principle, one can also measure the surface velocity with an intensity probe since this quantity may be approximated by the normal component of the particle velocity near the radiating structure, which may be determined using Eq. (12).³⁶ The advantage is that the sound intensity and the velocity are determined at the same time. However, in practice, such a velocity measurement can be problematic, among other reasons because of its sensitivity to extraneous noise,³⁷ and a conventional measurement with accelerometers or a laser transducer may be a better option.

6.4 Transmission Loss of Structures and Partitions

The conventional measure of the sound insulation of panels and partitions is the transmission loss (also called sound reduction index), which is the ratio of incident to transmitted sound power in logarithmic form. The traditional method of measuring this quantity requires a transmission suite consisting of two vibration-isolated reverberation rooms. The sound power incident on the partition under test in the source room is deduced from an estimate of the spatial average of the mean square sound pressure in the room on the assumption that the sound field is diffuse, and the

Figure 16 Interlaboratory comparison for a single metal leaf window (lower curves) and for a double metal leaf window (upper curves): (a) conventional method and (b) intensity method. (From Ref. 38. Reprinted with permission by Elsevier.)

transmitted sound power is determined from a similar measurement in the receiving room where, in addition, the reverberation time must be determined. The sound intensity method, which is now standardized,^{39,40} has made it possible to measure the transmitted sound power directly. In this case it is not necessary that the sound field in the receiving room is diffuse, which means that only one reverberation room, the source room, is necessary.⁴¹ One cannot measure the incident sound power in the source room using sound intensity since the method gives the *net* sound intensity. Figure 16 shows the results of a round-robin investigation in which a single-leaf and a double-leaf construction were tested by four different laboratories using the conventional method and the intensity-based method.

The main advantage of the intensity method over the conventional approach is that it is possible to evaluate the transmission loss of individual parts of the partition. However, each sound power measurement must obviously satisfy the condition expressed by inequality (26).

There are other sources of error than phase mismatch. To give an example, the traditional method of measuring the sound power transmitted through the partition under test gives the transmitted sound power irrespective of the absorption of the partition, whereas the intensity method gives the net power.⁴² If a significant part of the absorption in the receiving room is due to the partition, then the net power is less than the transmitted power because a part of the transmitted sound energy is reabsorbed/transmitted by the partition. Under such conditions one must increase the absorption of the receiving room; otherwise the intensity method will overestimate the transmission loss because the transmitted sound power is underestimated.

As an interesting by-product of the intensity method, it can be mentioned that deviations observed between results determined using the traditional method and the intensity method led several authors to reanalyze the traditional method in the 1980s^{43,44} and point out that the Waterhouse correction,⁴⁵ well established in sound power determination using the reverberation room method, had been overlooked in the standards for measurement of transmission loss.

6.5 Other Applications

The fact that the sound intensity level is much lower than the sound pressure level in a diffuse sound field has led to the idea of replacing a measurement of the *emission sound pressure level* generated by machinery at the operator's position by a measurement of the sound intensity level, because the latter is less affected by diffuse background noise.⁴⁶ This method has recently been standardized.⁴⁷

CHAPTER 46

NOISE AND VIBRATION DATA ANALYSIS

Robert B. Randall

School of Mechanical and Manufacturing Engineering
The University of New South Wales
Sydney, New South Wales, Australia

1 INTRODUCTION

Noise is often produced by the radiation of sound from vibrating surfaces. The noise can be related by a physical transfer function to the surface vibration. Analysis of the noise and vibration signals is usually done to extract parameters that best characterize the signals for the purpose of the practical application. These parameters often include root-mean-square (rms) values that can be used to assess signal strength or the potential of the noise or vibration to cause damage. In some cases, it is necessary to study the resonant response of excited structures or systems to which the signal is applied. In such cases, simple signal strength is not the only important factor but also how the noise and vibration is distributed with frequency. Hence, frequency analysis by fast Fourier transform (FFT) techniques and filters is often used.

In recognizing the impulsiveness of some noise and vibration signals, and their potential to cause and/or reveal damage to machinery, structures, and humans, a knowledge of statistical parameters such as kurtosis is valuable as a measure of impulsiveness. In addition, because the statistical distribution of local peak values is related to fatigue life of machinery and structures, methods of describing it are important. The relationship between two (or more) noise or vibration signals can be important, for example, to characterize the properties of a physical system by relating the applied excitation to the response of the system, or simply to determine if the signals are related. Thus methods of establishing such relationships, such as correlations, cross spectra, and frequency response functions, are of interest. Such noise and vibration signals being analyzed usually have wide frequency and dynamic ranges, and typical condenser microphones for noise signals and accelerometers for vibration signals must have suitable performance for their measurement.

2 SIGNAL TYPES

Many noise and vibration signals come from machines in operation. A simple machine such as a motor–pump set has a single rotating shaft (in sections joined by couplings), and some vibrations, such as those due to unbalance, are directly related to the shaft speed and phase locked to it. At constant speed the unbalance force will be sinusoidal, and the vibration response also largely at this same frequency. Because of nonlinearities in the structure and support, the response may contain sinusoidal components at higher harmonics (multiples) of the shaft speed, but will still be *periodic* with a period equal to one revolution. With two or

more independent shafts, such as with an aeroengine, the shaft-related signal will still be a sum of sinusoids, but no longer periodic. Such signals are known as *quasi-periodic*. In some other machines, for example, internal combustion engines, some vibration components, such as those due to combustion, are loosely tied to shaft speed, but not phase locked. Accordingly, there is an explosion in each cylinder every cycle, but the combustion events are not exactly repeatable. Such signals are known as *cyclostationary*. Yet other components, typically those associated with fluid flow, such as turbulent fluctuations and cavitation, are not tied to shaft speeds at all and are random, although they may be stationary; that is, their statistical properties are invariant with time. At this point it is also worth mentioning *pseudorandom* signals. These are formed by taking a section of random signal and repeating it periodically. Thus, over short time periods they appear random, but they are actually deterministic.

For constant operating conditions all the above signals may be considered stationary (at least if the various realizations are arranged with arbitrary zero times so that there is no reason why ensemble averages at one time should be different from those at other times), but in the more general case statistical parameters vary with time because of varying conditions, and the signals are then nonstationary. Typical examples are the noise from an aircraft flyover or the vibrations from a machine during run-up or coast-down. Such signals are typically analyzed by dividing them up into short quasi-stationary sections, and the changes in their parameters registered against time.

All the above signals are continuous and characterized by their local *power*, that is, the mean-square value averaged over a defined time interval, but a further class of signals can be categorized as *transients*, that is, single events starting and finishing with value (essentially) of zero. Transient signals are characterized by their *energy*, that is, the integral of their instantaneous power over their entire length, and it is important to recognize the different dimensions and units of their time and frequency representations. Shocks are of this type. Interpreting a squared signal as power requires explanation but can be seen by analogy with electrical power, the product of current and voltage. Thus power $P = IV = I^2R = V^2/R$ (where I = current, V = voltage, and R = resistance), and so the physical power is related to the square of the current or voltage signal through a constant impedance or admittance parameter. In a similar manner, sound power is related to the square of sound pressure or

particle velocity, and vibration acceleration power is often represented in terms of g^2 or $(\text{ms}^{-2})^2$.

Figure 1 shows how the above-mentioned signals may be classified, and Fig. 2 shows typical time- and frequency-domain representations of some signal types. *Stationary deterministic signals* are made up entirely of sinusoidal components, while *stationary random signals* have a spectrum distributed continuously with frequency. Sinusoids have a finite power concentrated at a single frequency, whereas the spectra of stationary random signals must be integrated over a finite frequency band to obtain finite power, and it is then appropriate to speak of a constant *power spectral density* (PSD) or power per hertz. Transients also have a spectrum distributed continuously with frequency, but as mentioned above the transient has finite energy

and the spectrum should be scaled in *energy spectral density* (ESD) or energy per hertz.

3 TIME-DOMAIN DESCRIPTIONS

3.1 Statistical Descriptors

Use can be made of basic statistics to extract characteristic parameters from the time signal directly. In the most general case we will be dealing with an ensemble of time signals arising from a random process, as illustrated in Fig. 3, and the statistical parameters are calculated as the “expected value,” or ensemble average, represented by the symbol $E[\cdot]$, at a given time.

This description can also be used for nonstationary signals. Thus the *mean value*, or simple average, is

Figure 1 Division of signals into the main categories.

Figure 2 Typical signals in the time and frequency domains.

Figure 3 Illustration of ensemble averaging.

given by the formula

$$x_m(t) = E[x(t)] \quad (1)$$

However, for stationary signals, as mentioned above, the statistical parameters are independent of the time at which they are evaluated, and so $x_m(t) = x_m$, often represented as the constant μ . As discussed in Chapter 13, provided the process is ergodic, the statistical parameters can be calculated from averages taken along the time record, so

$$\mu_T = \frac{1}{T} \int_0^T x(t) dt \quad (2)$$

which represents an average over T seconds, but the equivalence with the ensemble average applies as $T \rightarrow \infty$. Since the average is independent of time t , the integration can also be from $-T/2$ to $T/2$. In what follows, until the case of nonstationary signals is considered, stationary signals will be assumed and all definitions will use time-domain averages.

If the squared value of the signal is averaged, this gives the *mean square value*, which is the averaged signal power. Thus,

$$x_{ms} = \frac{1}{T} \int_0^T x^2(t) dt \quad (3)$$

To obtain a parameter with the same dimensions and units as the original signal, it is normal to take the square root of the mean-square value to obtain the root-mean-square, or rms, value; thus;

$$x_{rms} = \sqrt{\frac{1}{T} \int_0^T x^2(t) dt} \quad (4)$$

It is also convenient to evaluate the parameters of the signal once the mean value or *direct current (dc) component* has been removed. The power of the remainder is the *variance*, given by

$$x_{var} = \sigma^2 = \frac{1}{T} \int_0^T (x(t) - \mu)^2 dt \quad (5)$$

and its square root is the *standard deviation*:

$$\sigma = \sqrt{\frac{1}{T} \int_0^T (x(t) - \mu)^2 dt} \quad (6)$$

3.2 Probability

For the random signal $x(t)$ (e.g., one of the realizations in Fig. 3), consider a number of samples at small uniform intervals. The fraction of samples that are less than a particular value of x can be used to define the *probability distribution* $P(x)$, which is the probability that the random variable $x(t)$ is less than x . That is,

$$P(x) = \text{Pr}[x(t) < x] \quad (7)$$

where $P(x)$ must have the form shown in Fig. 4, which states that $x(t)$ is certain to be less than the maximum value x_{\max} [i.e., $P(x_{\max}) = 1$], and it can never be less than the minimum value x_{\min} [i.e., $P(x_{\min}) = 0$]. $P(x)$ can also be interpreted as the fraction of time $x(t)$ is less than x . The probability that $x(t)$ is between $x + \Delta x$ and x is obviously $P(x + \Delta x) - P(x)$, as also shown in Fig. 4.

The *probability density* $p(x)$ is defined as

$$p(x) = \lim_{\Delta x \rightarrow 0} \frac{P(x + \Delta x) - P(x)}{\Delta x} = \frac{dP(x)}{dx} \quad (8)$$

Figure 4 Probability distribution for a random signal with maximum value x_{\max} and minimum value x_{\min} .

Since $p(x) = dP(x)/dx$ and in the general case $P(\infty) = 1$ while $P(-\infty) = 0$, it is evident that

$$\int_{-\infty}^{\infty} p(x) dx = \int_{-\infty}^{\infty} dP(x) = [P(\infty) - P(-\infty)] = 1$$

that is, the total area under the probability density curve must always be 1.

For so-called Gaussian random signals with a *normal distribution*, as discussed in Chapter 13, the probability density function is given by the formula

$$p(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) \quad (9)$$

which is basically an e^{-x^2} curve centered on the mean value μ , scaled in the x direction in terms of the standard deviation σ , and in the y direction so as to make the total integral unity. It is depicted in Fig. 5 (for zero mean value μ).

The statistical parameters of a signal can be obtained from the probability density function by taking various moments (see Chapter 13), for example,

$$\mu = \int_{-\infty}^{\infty} xp(x) dx \quad (10)$$

Figure 5 Probability density functions for the Gaussian and Rayleigh distributions.

This is the first moment of the probability density function, and because the area under the curve is unity, it defines its center of gravity. It is obvious that for any symmetrical function, such as the Gaussian function of Eq.(9), the mean value will be at the line of symmetry.

Similarly, the variance is given by the second moment about the mean value, or

$$\sigma^2 = \int_{-\infty}^{\infty} [x - \mu]^2 p(x) dx \quad (11)$$

which corresponds to the *moment of inertia* about the mean value.

The third moment gives a parameter called the skewness, which is zero for symmetrical functions and large for asymmetrical functions, while the fourth moment (normalized by the square of the second moment to make it dimensionless) is called the kurtosis, and is large for “spiky” or impulsive signals because of the considerable weighting given to local spikes by taking the fourth power. The skewness and kurtosis are given by Eqs. (12) and (13), respectively:

$$S = \int_{-\infty}^{\infty} [x - \mu]^3 p(x) dx \quad (12)$$

$$K = \frac{\int_{-\infty}^{\infty} [x - \mu]^4 p(x) dx}{\sigma^4} \quad (13)$$

Note that in some references (e.g., Gardner¹), the kurtosis is defined in terms of the fourth cumulant, rather than moment, in which case 3 is subtracted from the value obtained from Eq. (13). An n th-order cumulant is defined such that it contains no components of lower order, which is not the case for moments. For Gaussian signals all cumulants of higher than second order are equal to zero.

3.3 Statistics of Peak Values

In the analysis of fatigue failure of materials, the important factor determining fatigue life is the number of stress reversals at various stress levels, and the fatigue properties are characterized by so-called $S-N$ curves (describing the number of stress reversals N at various stress levels S). The data are often acquired using constant-amplitude sinusoidal stress fluctuations but are to be applied in more general stress versus time scenarios, and so it is necessary to determine the statistics of peak values (reversals) of a stress signal (or a vibration signal to which stress is proportional). Narrow-band Gaussian signals, as described in Chapter 13, have the appearance of a sinusoid with randomly varying amplitude. The probability density function of the signal itself is given by Eq.(9), but as described in Chapter 13, the

probability density of the peak values is given by the Rayleigh distribution (density) with the formula

$$p_p(x) = \frac{x}{\sigma^2} \exp\left(-\frac{x^2}{2\sigma^2}\right) \quad (14)$$

This is depicted in Fig. 5, along with the underlying normal density function.

4 SPECTRAL ANALYSIS

From Fig. 2, it can be seen that the distinction between some signal types is much more apparent in the frequency than in the time domain, and moreover the frequency of a spectrum component will quite often localize its source, for example, the rate of tooth meshing of a particular pair of gears, so spectral analysis (frequency analysis) will be considered in some detail.

4.1 Fourier Analysis

The mathematical basis of frequency analysis is Fourier analysis. Fourier's original theorem stated that any periodic signal $g(t)$, repeating with period T , could be decomposed into a number, perhaps infinite, of sines and cosines with frequencies that are multiples of $1/T$, the fundamental frequency, that is,

$$g(t) = g(t + T) = \frac{a_0}{2} + \sum_{k=1}^{\infty} a_k \cos\left(\frac{k2\pi t}{T}\right) + \sum_{k=1}^{\infty} b_k \sin\left(\frac{k2\pi t}{T}\right) \quad (15)$$

The series decomposition is known as a Fourier series. The first (constant) term is the average value and is actually the cosine term for zero frequency. The scaling factor $\frac{1}{2}$ is so that the same formula can be used for it as for the other cosine terms.

The a_k and b_k terms are determined by correlating the signal $g(t)$ with the various sinusoids, and since the latter are all orthogonal, a nonzero result is only obtained for that part of $g(t)$ corresponding to the sinusoid being correlated. Thus:

$$a_k = \frac{2}{T} \int_{-T/2}^{T/2} g(t) \cos(2\pi f_k t) dt \quad (16)$$

and

$$b_k = \frac{2}{T} \int_{-T/2}^{T/2} g(t) \sin(2\pi f_k t) dt \quad (17)$$

where $f_k = k/T$.

The total component at frequency f_k is thus $a_k \cos(2\pi f_k t) + b_k \sin(2\pi f_k t)$, which can also be expressed as $C_k \cos(2\pi f_k t + \phi_k)$, and can further be decomposed in terms of complex exponentials as

$$\frac{C_k}{2} \exp\{j(2\pi f_k t + \phi_k)\} + \frac{C_k}{2} \exp\{-j(2\pi f_k t + \phi_k)\}$$

Each sinusoidal component of amplitude C_k has thus been replaced by a pair of rotating vectors, one of amplitude $C_k/2$ rotating at frequency f_k and with initial phase ϕ_k and the other of the same amplitude rotating at $-f_k$ and with initial phase $-\phi_k$. This leads to a two-sided spectrum with frequencies ranging from $-\infty$ to $+\infty$. An alternative form for Eq. (15) is thus

$$g(t) = \sum_{k=-\infty}^{\infty} \frac{C_k}{2} \exp\{j(2\pi f_k t + \phi_k)\} = \sum_{k=-\infty}^{\infty} A_k \exp(j2\pi f_k t) \quad (18)$$

where each A_k value for negative k is the complex conjugate of the value for positive k and A_k represents the value of each rotating vector at time zero. The equivalent of Eqs. (16) and (17) is then

$$A_k = \frac{C_k}{2} \exp(j\phi_k) = \frac{1}{T} \int_{-T/2}^{T/2} g(t) \exp(-j2\pi f_k t) dt \quad (19)$$

Multiplication by the unit vector rotating at $-f_k$ stops the component in $g(t)$ originally rotating at f_k , at time zero, causing it to integrate to its correct value A_k , while all other components continue to rotate and integrate to zero over the periodic time.

Figure 6b depicts the harmonic spectrum of a periodically repeated transient signal, and Fig. 6a shows that if the repetition period T is allowed to tend to infinity, the harmonic spacing $1/T$ approaches zero, and the spectrum becomes continuous. At the same time, the power approaches zero, but the energy is finite. The typical spectrum value at frequency f [by analogy with Eq.(19)] becomes

$$G(f) = \int_{-\infty}^{\infty} g(t) \exp(-j2\pi f t) dt \quad (20)$$

where there is no longer a division by T because the energy is finite, and the resulting time signal [by analogy with Eq.(18)] becomes

$$g(t) = \int_{-\infty}^{\infty} G(f) \exp(j2\pi f t) df \quad (21)$$

Equations (20) and (21) represent the forward and inverse *Fourier transforms*, respectively, for a transient. Note the relationship with the *Laplace transform*, which can be expressed as

$$G(s) = \int_0^{\infty} g(t) \exp(-st) dt \quad (22)$$

This is the same as Eq.(20) if $g(t)$ is causal (e.g., any physical impulse response function, which must have zero value for negative time), and for s evaluated along the imaginary axis where $s = j\omega = j2\pi f$. Thus the Fourier transform can be interpreted as a special case of the Laplace transform. Because of the similarities of Eqs.(20) and (21) (only the sign of the exponent

is different), there is much symmetry between forward and inverse Fourier transforms, and, for example, Fig. 6c shows that for a discretely sampled time function, its spectrum is periodic (by analogy with Fig. 6b). Combining Figs. 6b and 6c we get what is known as the *discrete Fourier transform* (DFT), which is discrete in both domains, and can be calculated digitally from

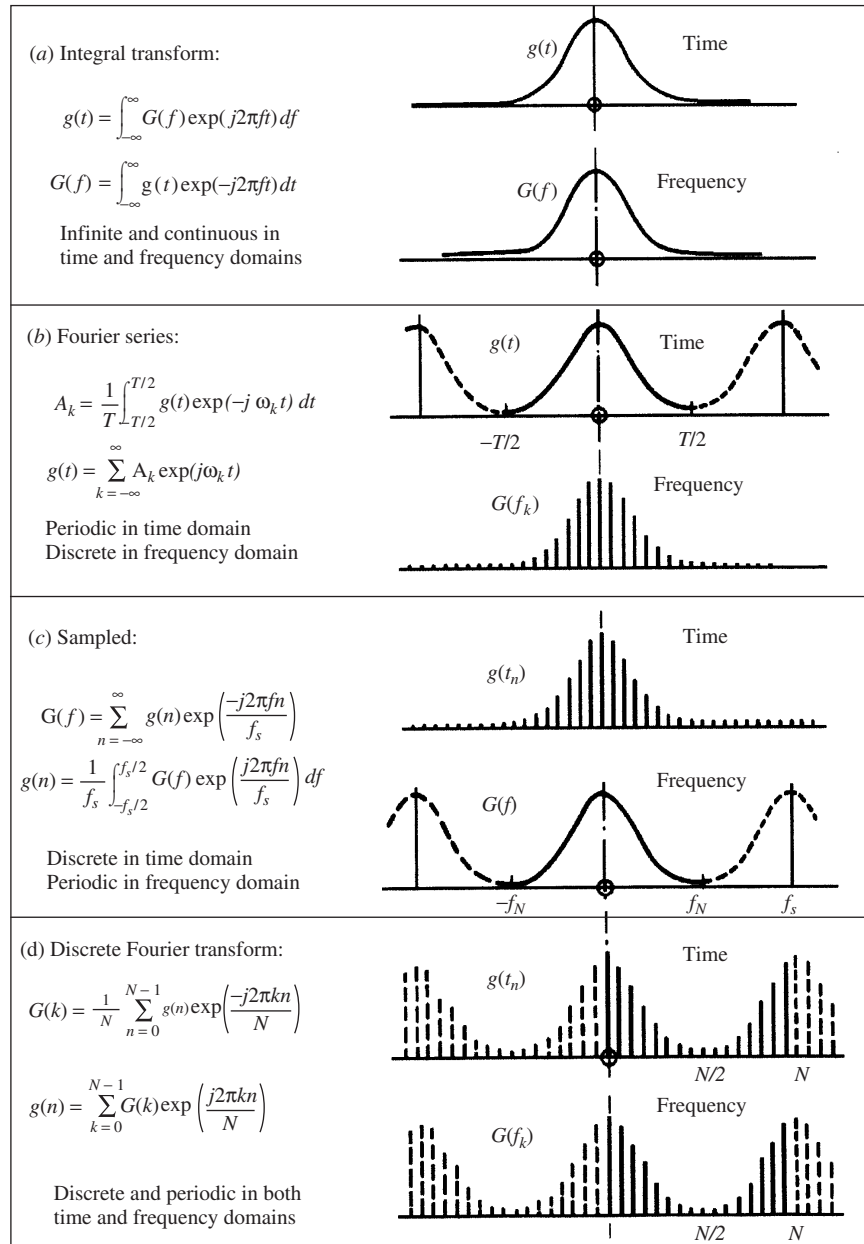

Figure 6 Various forms of the Fourier transform (a) Fourier integral transform, (b) Fourier series, (c) sampled functions, and (d) discrete Fourier transform.

a finite number of data. Note that it is also implicitly periodic in both domains, so that the frequency components in the second half of the spectrum equally represent the negative frequency components.

The equations for the forward and inverse DFT are as follows:

$$G(k) = \frac{1}{N} \sum_{n=0}^{N-1} g(n) \exp\left(-\frac{j2\pi kn}{N}\right) \quad (23)$$

and

$$g(n) = \sum_{k=0}^{N-1} G(k) \exp\left(\frac{j2\pi kn}{N}\right) \quad (24)$$

which gives N frequency values from N time samples, but for real-time signals there are only $N/2$ independent (though complex) frequency components from zero to half the sampling frequency. As mentioned above, the second half of the spectrum (the negative-frequency components) are the complex conjugates of the corresponding positive-frequency components. This version corresponds most closely to the Fourier series in that the forward transform is divided by the length of record N to give correctly scaled Fourier series components. If the DFT is used with other types of signals, for example, transients or stationary random signals, the scaling must be adjusted accordingly as discussed below. Note that with the very popular signal processing package Matlab, the division by N is done in the inverse transform, which requires scaling in every case, as even though the forward transform is then closer to the Fourier integral, it still must be multiplied by the discrete equivalent of dt .

The forward DFT operation of Eq.(23) can be understood as the matrix multiplication:

$$\mathbf{G}_k = \frac{1}{N} \mathbf{W}_{kn} \mathbf{g}_n \quad (25)$$

where \mathbf{G}_k represents the vector of N frequency components, the $G(k)$ of Eqs.(23) and (24), while \mathbf{g}_n

represents the N time samples $g(n)$. \mathbf{W}_{kn} represents a square matrix of unit vectors $\exp(-j2\pi kn/N)$ with angular orientation depending on the frequency index k (the rows) and time sample index n (the columns).

The so-called *fast Fourier transform*, or FFT, is just an extremely fast algorithm for calculating the DFT. It factorizes the matrix \mathbf{W}_{kn} into $\log_2 N$ matrices, multiplication by each of which only requires N complex multiplications. The total number of multiplications is thus reduced from the order of N^2 to $N \log_2 N$, a saving by a factor of more than 100 for a typical transform size of $N = 1024 = 2^{10}$.

4.2 Zoom FFT Analysis

The basic DFT transform of Eq.(23) extends in frequency from zero to the *Nyquist frequency* (half the sampling frequency) and has a resolution equal to the sampling frequency f_s divided by the number of samples N . Sometimes it is desired to analyze in more detail in a limited part of the frequency range, in which case use can be made of so-called *zoom analysis*. Since resolution $\Delta f = f_s/N$, the two ways to improve it are:

1. Increase the length of record N . In modern analyzers, and in signal processing packages such as Matlab, there is virtually no restriction on transform size, and so zoom can be achieved by performing a large transform and then viewing only part of the result.
2. Reduce the sampling frequency f_s . This can be done if the center of the desired zoom band is shifted to zero frequency so that the zoom band around the center frequency can be isolated by a low-pass filtration. The highest frequency is then half the zoom band, and the sampling frequency can be reduced accordingly without aliasing problems.

The latter process, known as *real-time zoom*, since the preprocessing normally has to be done in realtime, is illustrated in Fig. 7. The low-pass filtering and resampling process is usually done in octave (2:1)

Figure 7 Schematic diagram of FFT zoom process.

Figure 8 Use of FFT zoom to separate the harmonics of shaft speed from those of mains (line) frequency in an electric motor vibration spectrum. (a) Baseband spectrum with zoom band around 100 Hz highlighted and (b) zoom spectrum showing that twice mains frequency dominates over twice shaft speed.

steps, as a digital filter will always remove the highest octave, relative to the sampling frequency, and halving the sampling frequency simply means discarding every second sample (see discussion below of digital filters). If this is done in real-time by a specialized hardware processor, the sampling rate is reduced considerably before signals have to be stored, thus greatly conserving memory. Note that the time signal output from the zoom processor is complex, as the corresponding spectrum is not conjugate even.

Figure 8 shows an example of the use of zoom to separate the harmonics of shaft speed from those of mains frequency (U.S. line frequency) in the vibration signals from an induction motor. From the upper baseband spectrum it appears that the second harmonic of shaft speed is elevated. However, the lower zoom analysis centered on this frequency shows that it is the second harmonic of mains frequency that dominates (indicating an electrical rather than a mechanical fault), and the second harmonic of shaft speed is five times lower in level.

4.3 Practical FFT Analysis

The so-called *pitfalls* of the FFT are all properties of the DFT and result from the three stages in passing from the Fourier integral transform to the DFT. The first step is digitization of the time signal, which can give rise to *aliasing*; the second step is truncation of the record to a finite length, which can give rise to *leakage* or *window effects*; while the third results from discretely sampling the spectrum, which can give rise to the *picket fence effect*.

As explained in connection with Fig. 6, when a continuous time signal is sampled, it produces a

periodic spectrum with a period equal to the sampling frequency f_s . It can be seen that if the original signal contains any components outside the range $\pm f_N$, where f_N is the Nyquist frequency, then these will overlap with the true components giving “aliasing” (higher frequencies represented as lower ones). Once aliasing is introduced, it cannot be removed, so it is important to use appropriate analog low-pass filters before digitizing any time signal for processing. After initial correct digitization, digital low-pass filters can be used to permit resampling at a lower sampling rate.

With the DFT the signal is truncated to length T , which can be interpreted as multiplying it by a finite (rectangular) window of that length. By the convolution theorem, the spectrum is thus convolved with the Fourier transform of the window, which acts as a filter characteristic. Energy at a single frequency is spread into adjacent frequencies in the form of this characteristic, hence the term leakage. It can be advantageous to multiply the truncated segment with a different window function to improve its frequency characteristic and reduce leakage.

Finally, in the DFT the continuous spectrum is also discretely sampled in the frequency domain, which corresponds in the time domain to a periodic repetition of the truncated segment. The spectrum is not necessarily sampled at peaks, hence the term picket fence effect; it is as though the spectrum is viewed through the slits in a picket fence. Once again, use of another window function, other than rectangular, can reduce the picket fence effect, and in fact the so-called *flat-top* window virtually eliminates it.

4.4 Data Windows

A number of *data windows* (time windows when applied to time signals) have been developed for special purposes, depending on the type of signal being analyzed. As listed in Table 1, the main properties of the windows are their filter shape as characterized by their *noise bandwidth* (relative to the line spacing), the highest sidelobe, the rate of roll-off of the remaining sidelobes, and the maximum picket fence effect. The noise bandwidth is the width of an ideal (rectangular) filter that would transmit the same noise power for a white noise input, that is, having the same area under the amplitude squared characteristic. The table lists these properties for the most commonly used windows, and their time- and frequency-domain characteristics are shown in Fig. 9. The latter represent worst-case situations when the actual frequency is half way between two frequency lines. Otherwise, the sidelobes will not be sampled at their peaks. As an extreme example, when there is an integer number of periods in the record, the “ $\sin x/x$ ” characteristic of the rectangular window will be sampled at the zero crossings, and the sidelobes will not be apparent at all (thus corresponding to the fact that the periodic repetition will give an infinitely long sinusoid). Because of overlap, the frequency characteristics are also distorted when applied to a frequency near zero, or the Nyquist frequency. A good general-purpose window for continuous signals is the *Hanning* window,

Figure 9 Data windows for continuous signals: (a) rectangular, (b) Hanning, (c) Kaiser-Bessel, and (d) flat top.

one period of a \sin^2 function, as it has zero value and slope at each end and thus minimizes the discontinuity arising from joining the ends of the signal segment into a loop. Compared with a rectangular window, it has considerably improved filter characteristic, only slightly greater noise bandwidth, and much less picket fence error. The latter can easily be compensated for in

the case of sinusoidal components such as calibration signals.²

Where it is important to separate discrete frequency components, which are close together but of different levels, the *Kaiser-Bessel* window may be preferable to Hanning, but it has larger noise bandwidth. It should be kept in mind that separation of closely

spaced components may be better achieved using zoom analysis, as described above. For stationary deterministic signals, dominated by discrete frequency components, the best choice may be the flat-top window, mentioned above, as there is no need to compensate for picket fence error, also very valuable when using a calibration signal to calibrate the spectrum. Its noise bandwidth is very large, however, and so the discrete frequency components will not protrude so far from any noise in the spectrum (4 dB less compared with Hanning). This is because noise has a certain power spectral density, and the amount of noise power transmitted by a filter with larger bandwidth is greater, while the power in a sinusoidal component is independent of the filter bandwidth.

Windows are sometimes required in the analysis of transient signals also, such as in the hammer excitation of a structure for modal analysis purposes. The actual hammer force pulse will in general be very short, and it is common to place a short rectangular (so-called *transient*) window around it to remove noise in the rest of the record length. If the response vibration signals are shorter than the record length, there is no need to apply a window to the response acceleration traces. However, with lightly damped systems, the response may not decay to zero by the end of the (desired) record length. It is then necessary to either increase the record length (e.g., by zooming, which may require several analyses to cover the desired frequency range), or the signal can be forced to near zero at the end of the record by use of an *exponential* window. Multiplication by an exponential window corresponds to the addition of extra damping, which is known exactly, and so can be subtracted from the results of any measurements. A short taper, typically of a half-Hanning shape, can be added to both the leading and trailing edges of a transient window and to the leading edge of an exponential window, to make the transitions less abrupt.

4.5 Scaling of FFT Spectra

For a typical sinusoidal component $C_k \cos(2\pi f_k t + \phi_k)$ the instantaneous power is given by squaring it to

$$\begin{aligned} C_k^2 \cos^2(2\pi f_k t + \phi_k) \\ = C_k^2 \left\{ \frac{1}{2} + \frac{1}{2} \cos[2(2\pi f_k t + \phi_k)] \right\} \end{aligned}$$

and the average power or mean-square value is thus $C_k^2/2$ since the sinusoidal part averages to zero. Since $|A_k| = C_k/2$, the mean-square value is also given by $2|A_k|^2$ (i.e., the value obtained by adding the positive- and negative-frequency contributions) and the rms value by $C_k/\sqrt{2}$ and $\sqrt{2}|A_k|$, respectively. This illustrates one aspect of *Parseval's theorem*, which states that the total power can be obtained by adding the mean-square values of all components in the time domain (because they are orthogonal, the square of the sum equals the sum of the squares), or the squared amplitudes of all components in the (two-sided) frequency domain.

When scaled as in Eq. (23), the $G(k)$ resulting from the DFT (or FFT) is the A_k for the Fourier series of the periodically repeated signal segment. If the signal is genuinely made up of sinusoidal components, the measured $|A_k|$ should be multiplied by $\sqrt{2}$ to obtain the corresponding rms value or by 2 to obtain the sinusoidal amplitude. Most FFT analyzers would compensate for the reduction in power given by multiplication by a window (for Hanning this is achieved by scaling it to a maximum value of 2), although separate compensation may have to be made for picket fence error unless a flat-top window is used. A general way of determining the scaling effect of a window is to apply it to a sinusoid of known amplitude (with an integer number of periods in the record length), and scale the whole spectrum so that the maximum peak in the spectrum reads the correct value (possibly scaled to rms at the same time).

For stationary random signals, each record transformed will be treated by the DFT algorithm as a periodic signal, but the power in each spectral line can be assumed to represent the integral of the PSD over the frequency band of width $\Delta f (= 1/T)$, and thus the average PSD is obtained by multiplying the squared amplitude by T . The required averaging over a number of records does not change this scaling. How well the average PSD represents the actual PSD depends on the width of peaks (and valleys) in the spectrum. The width of such peaks is typically determined by the damping associated with a structural resonance excited by the broadband random signal, and the 3-dB bandwidth is given by twice the value of σ (expressed in Hz), where σ (expressed in rad/s) is the coefficient of exponential damping $\exp(-\sigma t)$ for the resonance in question. The PSD will be sufficiently accurate if the 3-dB bandwidth is a minimum of five analysis lines. If a window such as Hanning has been used to reduce leakage, and if it is scaled so as to read the peak value of discrete frequency components (as recommended above), the calculated PSD value will have to be divided by the "noise bandwidth" indicated in Table 1 to compensate for the extra power given by the spectral sidebands.

Transient signals are also treated as being one period of a periodic signal, so not only does the power in a spectral line have to be converted to an average spectral density by dividing by Δf , but also the average power must be converted to energy per period by a further multiplication by T , altogether a multiplication by T^2 to obtain a result scaled as ESD.

Table 1 Properties of Various Windows

Window	Noise Bandwidth	Highest Sidelobe (dB)	Sidelobe Roll-off (dB/decade)	Picket Fence Effect (dB)
Rectangular	1.0	-13	20	3.9
Hanning	1.5	-33	60	1.4
Kaiser-Bessel	1.8	-60	20	0.8
Flat top	3.8	-70	20	<0.1

Generally, transient signals will be shorter than the transform length, and thus a rectangular window will be used, and if the signal has decayed to near zero at the end of the record (possibly by using an exponential window), the signal bandwidth will be sufficiently greater than the analysis bandwidth for the average ESD to represent the true ESD. The extra damping given by an exponential window will genuinely give a reduction in signal energy.

4.6 Spectrum Averaging

The need for averaging of FFT spectra is determined by whether the signal contains random components or not. Averaging should always be done in terms of signal power (i.e., amplitude squared) as it is this that is conserved independent of phase. The DFT spectra of discrete frequency components always have the same amplitude, and therefore little is achieved by averaging the squared amplitudes, although a small number of averages may be useful for clarifying which components are discrete frequency and which are random.

When meaningful spectra are to be obtained from random signals, which in mechanical signals are typically caused by fluid flow (turbulence, cavitation), road roughness, and the like, it is necessary to average a number of power spectrum estimates. The number of averages required is determined by the desired accuracy, as the standard deviation of the result (for Gaussian signals) is given by²

$$\varepsilon = \frac{1}{2\sqrt{n}} \quad (26)$$

where n is the number of independent averages. Thus, for $n = 16$, $\varepsilon = 12.5\%$ or 1 dB, meaning that there is a 68% probability that the result will be within ± 1 dB, 95% probability that it will be within ± 2 dB, and 99.7% probability that it will be within ± 3 dB. To halve the error it is necessary to make four times as many averages and so forth.

With a rectangular window, “independent” means nonoverlapping, but with other windows such as Hanning, advantage can be gained by overlapping, as information is lost near the two ends where the weighting is near zero. In fact, very little is lost statistically by overlapping 50%, and so this is recommended for stationary random signals, as twice as many effective averages can be obtained from a given length of signal. The overall weighting is not uniform in that case, but this gives no problem for stationary signals. To extract all information from a given length of record, in particular if it is nonstationary, it is advisable to overlap by a factor of at least $\frac{2}{3}$, although with typical FFT record lengths in powers of 2 it is often simpler to overlap by $\frac{3}{4}$. In the latter case the effective number of averages to insert in Eq. (26) is half the actual number. The Matlab function PSD performs overlap averaging, but the scaling should be checked by trial and error on a known signal.

4.7 Spectral Analysis Using Filters

Before the advent of the FFT algorithm, most frequency analysis was done using analog filters to filter the signal in a series of contiguous filter bands, measuring the output of each filter with an rms detector.² Constant bandwidth filters were produced by a frequency shifting “heterodyne” process, but these have now been completely replaced by digital FFT analysis, at least in the audio frequency range. However, FFT spectra give constant resolution on a linear frequency scale, and this automatically gives a restriction in frequency range since the upper decade occupies 90% of the scale. Much frequency analysis for acoustical purposes is required to be octave-based on a logarithmic frequency axis since this better matches the response of the human ear. The ear interprets frequency intervals of one octave (ratio 2 : 1) as equal changes, and steps of one-third-octave (ratio $2^{1/3}$: 1) as significantly different for narrow-band noise. The $1/n$ octave bands are *constant percentage bandwidth* (CPB), with equal resolution on a logarithmic axis, and allow depiction of a spectrum over a number of decades, for example, the nominal audio range of 20 Hz to 20 kHz. Since $2^{10} = 1024$, ten octaves are very close to three decades, and in fact the center frequencies of the standard one-third octave filters are adjusted slightly to correspond to one-tenth decades, with 10 filters between 100 Hz and 1 kHz, or between 1 kHz and 10 kHz. An octave band filter has bandwidth 70.7% (relative to the center frequency) and one-third octave 23.1%.

For filter bandwidth B in hertz, the filter response time is of the order of $1/B$, and thus it is necessary to wait at least this amount of time to obtain a result, even for deterministic signals. The resulting BT product of 1 corresponds to that for FFT analysis, where each spectrum of bandwidth B comes from a record length $T = 1/B$. For random signals, the BT product must be greater to give a spectrum value with reasonable confidence, and the equivalent of Eq. (26) is

$$\varepsilon = \frac{1}{2\sqrt{BT}} \quad (27)$$

where T represents the averaging time. Since the bandwidth of CPB filters increases with frequency, the standard error ε decreases correspondingly if the averaging time is constant. RMS detectors used with analog filters usually include the equivalent of RC smoothing circuits, with time constant equal to the product of circuit resistance R and capacitance C . As shown in Randall,² they give exponential averaging (by convolution with the exponentially decaying impulse response of the circuit) where the effective linear equivalent averaging time (on stationary signals) is $2RC$. However, their peak output for impulsive inputs is twice that of the running linear averager with the same averaging time, and account must be taken of this when frequency analyzing short transients.²

Digital filters can be designed to be similar to analog filters in that the output signal is convolved with the impulse response of the filter, and operate directly in the time domain on continuous (though sampled) signals (as opposed to the blockwise treatment of the FFT process). The coefficients that define the filter properties give a characteristic that is defined in relation to the sampling frequency. Thus, three sets of filter coefficients will define the one-third octave filters in one octave, but halving the sampling frequency will produce the equivalent filters one octave lower. Before halving the sampling frequency, the signal must be low-pass filtered by a filter that removes the upper octave of frequency information, but this can also be done by a digital filter with the same coefficients for every octave. When the sampling frequency is repeatedly halved for each octave, the total number of samples to be treated per unit time = $M(1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \dots) = 2M$ samples so that if the digital filter processor is capable of operating twice as fast as necessary for the highest octave, any number of lower octaves can be processed in real time. This feature was mentioned in conjunction with the zoom processor of Fig. 7.

Constant percentage bandwidth spectra can also be obtained by conversion from FFT spectra, as illustrated Fig. 10, where each decade is converted separately. The bandwidth of the individual lines in the original FFT spectra (including the effect of any window) must be less than the percentage bandwidth being converted to at the lowest frequency in the FFT band. The conversion is achieved by calculating the lower and upper cutoff frequencies of each constant percentage band, and then integrating up the power in the FFT lines (and parts of lines) between the limits. The method indicated in Fig. 10 gives a large change in filter characteristic at the junction between decades, and this can be a problem with acoustic spectra, which often have to satisfy standards with respect to filter characteristics. To reduce the latter problem, some FFT analyzers do the conversion on an octave rather than a decade basis.

Figure 10 Conversion from FFT spectra to a CPB spectrum.

5 TIME-DOMAIN ANALYSIS

5.1 Correlation Functions

The *cross-correlation function* gives a measure of how well one signal correlates with a delayed version of the other, as a function of the delay (so-called *lag*). For random processes, the cross correlation is defined as an ensemble average, and for nonstationary processes is a function of evaluation time and time lag, namely

$$R_{xy}(t, \tau) = E[x(t - \tau/2)y(t + \tau/2)] \quad (28)$$

For stationary signals the result is independent of time t , and the average can be carried out over time, namely

$$R_{xy}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} x\left(t - \frac{\tau}{2}\right) y\left(t + \frac{\tau}{2}\right) dt \quad (29)$$

The *autocorrelation function* occurs when $x(t)$ and $y(t)$ are the same, giving the corresponding equations for nonstationary and stationary processes as

$$R_{xx}(t, \tau) = E\left[x\left(t - \frac{\tau}{2}\right)x\left(t + \frac{\tau}{2}\right)\right] \quad (30)$$

and

$$R_{xx}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} x\left(t - \frac{\tau}{2}\right)x\left(t + \frac{\tau}{2}\right) dt \quad (31)$$

or

$$R_{xx}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} x(t)x(t + \tau) dt \quad (32)$$

Strictly speaking, the Fourier transform of Eq. (20) is not defined for random signals, even though a procedure was given in the last section for estimating their PSD spectra by averaging the power spectra of a number of realizations of the signal obtained using the FFT. It can be shown (the so-called Wiener-Khinchin relations) that the power spectrum of a random signal is the Fourier transform [using Eq. (20)] of the autocorrelation function given by Eq. (31) or (32), and this provides another way of estimating it, though the FFT procedure is much more efficient. The autocorrelation function can be normalized to a maximum value of unity, by dividing the function by the value for $\tau = 0$, which will be seen to be the mean-square value.

The cross-correlation function can be used to determine to what extent one signal is a delayed version of another (if it is just that, the result will be the autocorrelation function with its peak at the delay time, while if it is similar but not identical there will

still be a peak but with a lower value of correlation). The autocorrelation function gives a measure of the *correlation length* of a signal, and will have peaks corresponding to the delay times of any echoes. Note that the effective length of an autocorrelation function is inversely proportional to its frequency bandwidth, so it is only for wideband signals that there will be distinct peaks in the correlation functions corresponding to the delays. The autocorrelation function for white noise (uniform PSD) is a delta function at zero time lag. Note that the cepstrum² in principle has delta functions corresponding to echo delay times, independent of the bandwidth, and is thus better than the autocorrelation for this purpose.

5.2 Time Synchronous Averaging

This is useful for extracting that part of a signal that is periodic with the same period as a trigger signal, for example, a once-per-revolution tacho signal from a shaft in a rotating machine. In practice, it is done by averaging together a series of signal segments each corresponding to one period of the synchronizing signal. Thus

$$y_a(t) = \frac{1}{N} \sum_{n=0}^{N-1} y(t + nT) \quad (33)$$

This can be modeled as the convolution of $y(t)$ with a train of N delta functions displaced by integer multiples of the periodic time T , which corresponds in the frequency domain to a multiplication by the Fourier transform of this signal, which can be shown to be given by the expression³

$$C(f) = (1/N) \sin(N\pi T f) / \sin(\pi T f) \quad (34)$$

The filter characteristic corresponding to this expression is shown in Fig. 11 for the case where $N = 8$ and is seen to be a comb filter selecting the harmonics of the periodic frequency. The greater the value of N the more selective the filter, and the greater the rejection of nonharmonic components. The noise bandwidth of the filter is $1/N$, meaning that the improvement in signal-noise ratio is $10 \log_{10} N$ dB for additive random noise. For masking by discrete frequency signals, it

Figure 11 Filter characteristic for eight averages. (From Ref. 3. Reprinted by permission of Elsevier.)

should be noted that the characteristic has zeros that move with the number of averages, so it is often possible to choose a number of averages that completely eliminates a particular masking frequency.³

For good results the synchronizing signals should correspond exactly with samples of the signal to be averaged, as one sample spacing corresponds to 360° of phase of the sampling frequency, and thus to 144° of phase at 40% of it, which is a typical maximum signal frequency. Moreover, even a 0.1% speed fluctuation would cause a jitter of the same order of the last sample in a (typical) 1000-sample record, with respect to the first, and thus an even greater loss of information at the end of the record, after averaging. Sampling the signal using a sampling frequency derived from the synchronizing (tacho) signal solves both these problems and is always to be recommended. The best method is to digitally resample each record based on the corresponding period of the tacho signal. This can be done in a number of ways, based on digital interpolation, for example, using cubic splines or the method of Ref. 4.

6 ANALYSIS OF CYCLOSTATIONARY SIGNALS

Cyclostationary signals are the subject of increasing interest in vibration analysis since it has been realized that many machine vibration signals are not simply periodic but cyclostationary. The definition of cyclostationarity at the n th order is that the n th order statistics are periodic. Thus, a first-order cyclostationary signal has periodic mean value, while a second-order cyclostationary signal has periodic autocorrelation function [this being defined by the time-varying ensemble average of Eq. (28)]. A typical second-order cyclostationary signal is amplitude modulated white noise, as shown in Fig. 2. It is obvious that an ensemble average of its variance (autocorrelation for $\tau = 0$) will be periodic, and proportional to the square of the modulating function. A less obvious example of a second-order cyclostationary signal is frequency-modulated narrow-band noise, such as might arise as the response of a resonant system with periodically varying stiffness when excited by a white noise.

Many machine vibration signals are a mixture of first- and second-order cyclostationary components, such as the combustion pressure signal in each cylinder of an engine. There is an explosion every cycle, but not identical, so it can be divided up into the (ensemble) mean pressure (first-order cyclostationary) and the fluctuations around the mean, an amplitude-modulated noise (second-order cyclostationary) that averages to zero. In terms of noise generation these might be equally important. Another example is the vibrations generated by an extended spall in the inner race of a rolling element bearing, where the rollers are in a different position on the rough spalled surface for every rotation of the inner race. This can also be divided into first- and second-order components.

By definition, the autocorrelation function for a second-order cyclostationary signal is periodic with time t , though transient with time lag τ (as for

Figure 12 Spectral correlation and spectrum of squared envelope for a bearing fault signal.

any stochastic signal). Thus, if Fourier transforms are performed in the two directions, the transform in the τ direction will give a continuous spectrum against normal frequency f , while that in the t direction (actually a Fourier series because of the periodicity) will give a discrete spectrum against so-called *cyclic frequency* α . The result of the two-dimensional Fourier transform is the so-called *spectral correlation*. Figure 12a shows the spectral correlation for the vibration signal from a faulty bearing. It is seen to have the form of a second-order cyclostationary signal, being continuous against f while discrete against α . Also shown in Fig. 12b is the integral of the spectral correlation over all f , which is shown in Ref. ⁵ to be the same as the spectrum of the squared envelope of the original time signal (i.e., the expected value of the square of the signal). This is useful for quantifying periodicity of a signal envelope, even where the signal has zero mean value. If the discrete frequency components are first removed from a signal, the spectral correlation calculated for specific cyclic frequencies can indicate whether second-order cyclostationarity exists at this frequency. The application of this to bearing diagnostics is explained in Chapter 48.

If only the first Fourier transform of the two-dimensional autocorrelation function from τ to f is performed, the result is a time–frequency diagram related to the Wigner–Ville distribution (WVD), which

is for a single realization rather than an ensemble average. It is known as the Wigner–Ville spectrum, or instantaneous spectrum, and has the advantage that if only second-order cyclostationary components are present, the interference components that give problems with the WVD tend to average to zero since they come with random phase. The application of this to diesel engine vibration signals is illustrated in Chapter 48.

7 MULTIPLE-CHANNEL ANALYSIS

For system analysis, it is normally necessary to measure both input and output signals at the same time and process them in pairs to obtain transfer function information, such as frequency response functions (FRFs). With multiple inputs and/or outputs, it can be necessary to process more than two signals at a time, by matrix methods, but that will not be considered in detail here, as it is covered in other chapters.

8 THE CROSS SPECTRUM

The cross spectrum between two signals $a(t)$ and $b(t)$ is obtained by multiplying $G_b(f)$, the spectrum of the second, by the complex conjugate of $G_a(f)$, the spectrum of the first (this being considered as the input since the phase of the result has its phase as datum). As with the autospectrum, to which it reduces if the two signals are identical, for random signals

the individual estimates must be averaged to obtain meaningful results. Thus

$$G_{ab}(f) = E[G_a^*(f)G_b(f)] \quad (35)$$

By the Wiener–Khinchin relationship, the cross-spectrum is the Fourier transform of the cross correlation function between $a(t)$ and $b(t)$, that is,

$$G_{ab}(f) = \mathfrak{F}\{R_{ab}(\tau)\} \quad (36)$$

This, of course, reverts to the power spectrum or autospectrum when the signals are identical, as mentioned in Section 5.1.

9 FREQUENCY RESPONSE FUNCTION

In the frequency domain the FRF is basically the ratio of output over input, or

$$H_{ab}(f) = \frac{G_b(f)}{G_a(f)} \quad (37)$$

but in the presence of noise, better estimates can be obtained by a process of least squares noise reduction. If noise is primarily located in the output signal (over which the experimentalist has less control), the procedure is modified by multiplying numerator and

denominator by the complex conjugate of the input spectrum, and averaging, to give

$$H_1(f) = \frac{E[G_b(f)G_a^*(f)]}{E[G_a(f)G_a^*(f)]} = \frac{G_{ab}(f)}{G_{aa}(f)} \quad (38)$$

since averaging reduces the effect of noise on the cross spectrum (and the input autospectrum is noise free).

If noise is primarily located in the input signal, a better estimate is given by

$$H_2(f) = \frac{E[G_b(f)G_b^*(f)]}{E[G_a(f)G_b^*(f)]} = \frac{G_{bb}(f)}{G_{ba}(f)} \quad (39)$$

The system impulse response function can be obtained by inverse transformation of the FRF.

10 COHERENCE

The coherence gives a measure of the degree of linear relationship between two signals as a function of frequency. It is calculated by the formula

$$\gamma^2(f) = \frac{|G_{ab}(f)|^2}{G_{aa}G_{bb}} \quad (40)$$

This may be recognized as the square of the correlation coefficient between input and output spectral components at each frequency. It has values between

Figure 13 Example of FRFs (H_1 and H_2) measured using random excitation with a shaker and the corresponding coherence.

zero and one depending on the degree of linearity. For a single estimate, it will always be one, since $|G_{ab}| = |\bar{G}_a| \cdot |\bar{G}_b|$. In the absence of noise and nonlinearity, each estimate of G_{ab} will have the same amplitude and orientation so that the average value will not change. However, in the presence of noise and/or nonlinearity the various estimates will change in length and particularly phase, so that the average obtained by vector summation will be less than if they were aligned and the value of the coherence drops below one. If there is no linear relationship, the various estimates will have random orientation and the average will tend to zero. It can be shown that the coherence is also given by

$$\gamma^2(f) = \frac{H_1(f)}{H_2(f)} \quad (41)$$

The coherence is very useful for judging the validity of FRFs and is much used in modal analysis (see Chapter 47).

An example of FRFs measured between two points on a rectangular brass plate is given in Fig. 13. It shows H_1 , H_2 , and the coherence for measurements made with a shaker applying a random excitation (measured with a force transducer) and response measured using an accelerometer. Hanning windows were applied to both input and output signals. Also shown at the bottom is the coherence for this measurement. This is seen to be close to unity for most of the frequency range, but lower in the vicinity of resonance and antiresonances. The reason for the drop is different for the two cases. Near antiresonances, the coherence is low because the response signal is weak and masked by noise; thus H_1 gives a good estimate in these regions. Near resonances, the coherence is reduced because of *resolution bias error*, basically a nonlinearity caused by leakage, since the resonance peaks are not sufficiently resolved by the Hanning window used. Because the width of resonance peaks tends to be proportional to the frequency (for constant relative damping), it is seen that the error is greater for the lower frequency resonances. Even so, for all resonances, a better estimate of their peak values would be given by H_2 , as it can be shown that this is

less sensitive to resolution bias error.² Resolution bias error can be eliminated by zooming on the resonance peaks so that their width is greater than that of the Hanning window.

CHAPTER 47

MODAL ANALYSIS AND MODAL TESTING

David J. Ewins
Mechanical Engineering Department
Imperial College London
London, United Kingdom

1 INTRODUCTION

Modal analysis is a term used to describe any of the processes employed to extract a structure's modal properties (natural frequencies, modal damping factors, and mode shapes) from information about the structure that is presented in a different format. When these properties are extracted from a theoretical analysis of the dynamic behavior, the modal analysis process involves computation of the modal properties from a set of equations of motion that have been written in terms of the individual mass and stiffness elements that make up the mathematical model of the structure (usually, a finite element model).

However, there is another important interpretation of the term modal analysis that is discussed here and that refers to the extraction of the same modal properties from measured data—usually response characteristics—rather than from a theoretical mathematical model. This approach is known as experimental modal analysis and is often referred to as modal testing, partly to avoid any confusion with theoretical modal analysis, but also to indicate quite clearly that it is concerned with measured data. So, *experimental modal analysis* is a methodology that enables a structure's modal properties to be determined from experimental observations of its dynamic response under test conditions. In fact, a more precise definition of modal testing is *the construction, using data measured on a test structure, of a mathematical model that describes the structure's dynamic behavior under a range of excitation conditions*. From this definition, it can be clearly deduced that the objective of experimental modal analysis is the construction of a mathematical model.

2 THEORETICAL BASIS

2.1 Models for Structural Dynamics Analysis

In order to help set experimental modal analysis into perspective with respect to theoretical methods, it is helpful to discuss three different types of mathematical model that are used to describe a structure's dynamics and to show their interdependence (Fig. 1).

First is the *spatial model*, which describes the distribution in space of the mass, stiffness, and damping properties of the structure. Mathematically, the spatial model comprises three matrices: the mass matrix $[M]$, the stiffness matrix $[K]$, and—when the information is available—a damping matrix $[C]$. The unknown variables in the equations of motion written in terms of the spatial model are the time-varying displacements, $\{x(t)\}$, of the various degrees

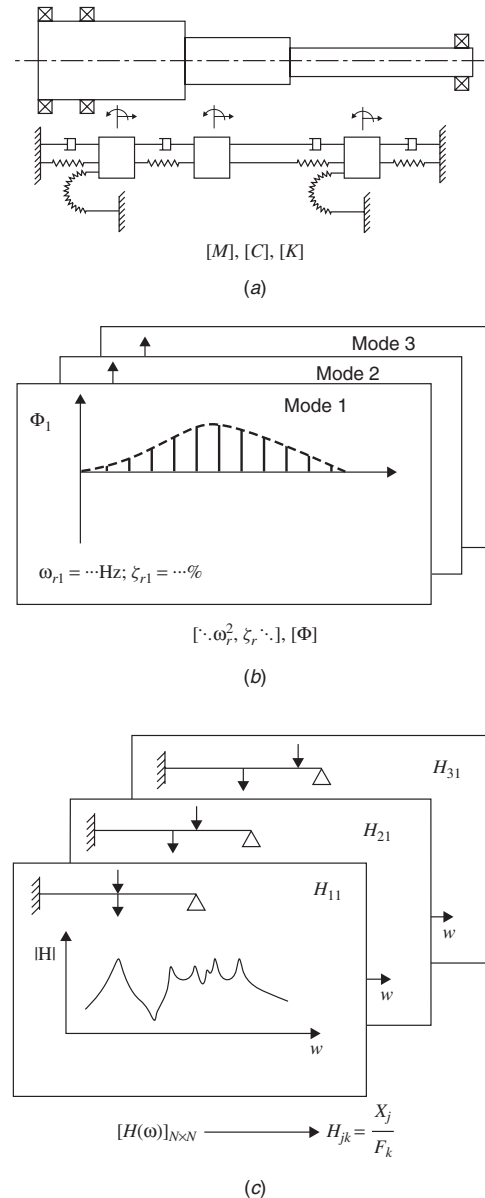

Figure 1 Types of mathematical models for dynamic analysis of structures: (a) spatial model, (b) modal model, and (c) response model.

of freedom (DOFs), which are used to describe the system's motion in response to a set of prescribed time-varying excitation forces, $\{f(t)\}$, applied at the same DOFs:

$$[M]\{x''(t)\} + [C]\{x'(t)\} + [K]\{x(t)\} = \{f(t)\} \quad (1)$$

The second type is the *modal model*, and this presents an alternative description of the dynamic behavior, expressed in terms of the fundamental (or "normal") vibration modes that represent the structure's natural (i.e., free or unforced) vibration behavior. This model comprises an eigenvalue matrix, containing the natural frequencies and modal damping factors, $\text{diag}[\omega_r^2; \zeta_r]$, and an eigenvector, or mode shape, matrix, $[\Phi]$. The equations of motion expressed using the modal model have as unknown quantities the magnitudes of response in each of the constituent modes, $\{p(t)\}$, resulting from the application of a set of modal excitation functions, $\{P(t)\}$:

$$[I]\{p''(t)\} + \text{diag}[2\zeta_r\omega_r]\{p'(t)\} + \text{diag}[\omega_r^2]\{p(t)\} = \{P(t)\} \quad (2)$$

The third model is the *response model*, and this describes the structure's dynamic behavior directly in terms of a specific characteristic response parameter, such as the frequency response function (FRF). Here, the equations of motion comprise a single matrix of FRFs, $[H(\omega)]$, with the harmonic responses at all DOFs as the unknown variables, $\{X(\omega)\}$, resulting from a matching set of harmonic excitation forces, $\{F(\omega)\}$. This response vector is sometimes referred to as an *operational deflection shape* and the corresponding equation is

$$[H(\omega)]\{F(\omega)\}e^{i\omega t} = \{X(\omega)\}e^{i\omega t} \quad (3)$$

The typical individual FRF is generally written as $H_{jk}(\omega)$ and can be defined as X_j/F_k , where a single harmonic excitation force is applied at DOF k [$f_k(t) = F_k e^{i\omega t}$; $f_{1,2,3,\dots \neq k}(t) = 0$], and the resulting harmonic response at DOF j is $x_j(t) = X_j e^{i\omega t}$. This type of FRF is called a *receptance*, while other versions include *mobility* (when the response parameter is velocity rather than displacement) or *accelerance* when acceleration response is used.

2.2 Essential Theory of Experimental Modal Analysis

There are relatively simple mathematical expressions that interconnect these three models. Each model contains the same essential information as the others, unless there is a truncation (elimination) of certain data, in which case they provide different approximations to the structure that they all represent. In these circumstances, it is extremely important to understand the implications of such truncation. Because, in experimental activities, we are almost always obliged to

restrict the quantity of data that are measured, the probability of seeking to construct a mathematical model with incomplete data is relatively high. As a result, it is important that any discussion of modal testing is prefaced by an outline of the theoretical basis of the approach, and of the potential difficulties that may be encountered. The relevant mathematical relationships (subject to certain simplifying assumptions that are adopted here to retain a degree of simplicity in the expressions) are shown below:

$$[\Phi]^T[M][\Phi] = \text{diag}[I]; [\Phi]^T[K][\Phi] = \text{diag}[\omega_r^2] \quad (4)$$

$$[H(\omega)] = ([K] + i\omega[C] - \omega^2[M])^{-1} \quad (5)$$

$$[H(\omega)] = [\Phi]\text{diag}[(\omega_r^2 - \omega^2 + 2i\omega\omega_r\zeta_r)]^{-1}[\Phi]^T \quad (6)$$

$$H_{jk}(\omega) = \Sigma(\phi_{rj})(\phi_{rk})/(\omega_r^2 - \omega^2 + 2i\omega\omega_r\zeta_r) \quad (7)$$

Further details can be found in Refs. 1–4.

If it is required to determine a structure's modal properties from experimental measurements, then it is necessary to understand the theoretical basis of the processes used. The underlying theory for experimental modal analysis can be summarized by reference to the different mathematical models introduced in the previous section. In practice, the only parameters that can be measured directly are the time-varying quantities of excitation force and resulting response: $\{f(t)\}$ and $\{x(t)\}$. The response model is the one that applies most directly to the situation in a modal test, and the most immediate output that is available from such a procedure will be a set of response functions. These will usually be FRFs as a result of the convenience of measuring and calculating responses to harmonic excitations. (However, it should be noted that a similar approach is possible with other types of standard response function, such as the impulse response function, or IRF.) Thus, in order to determine the natural frequencies and mode shapes, it is necessary to extract the required modal parameters from the measured response functions. This process is sometimes called *modal analysis* and sometimes *modal parameter extraction* and forms the heart of the postmeasurement stage of a modal test. In effect, we seek to construct a modal model by measuring data that allows us to "measure" a response model using the mathematical relationships shown above.

3 OBJECTIVES AND APPLICATIONS OF EXPERIMENTAL MODAL ANALYSIS

As mentioned in the previous section, the primary objective of modal testing is the construction of a mathematical model of the test structure from tests carried out under controlled conditions. Such a model is useful for a range of specific applications, including (but not limited to) those outlined below.

3.1 Model Validation

The most common application of a test-derived model is to validate a theoretical model, usually a finite

element description, that has been constructed for design purposes. This application involves a series of well-defined and interrelated steps that include:

1. Comparison of predicted and measured properties
2. Correlation of these properties to quantify their similarities/differences
3. Reconciliation of the two sets of results by identifying why they differ
4. Adjustment of one or other set of results so that they agree

At the conclusion of this last stage, the theoretical model can be deemed to have been validated, at least for further application in the range of frequencies and/or DOFs that have featured in the tests.

3.2 Diagnostics

In a similar vein, the same type of model can be used in a wide range of diagnostics applications, in particular to monitor changing patterns of behavior with continued running of a machine. The ability to interpret changes in behavior with the aid of a model of the structure means that sources of the changes can be identified, and early diagnosis of deterioration in the structure made.

3.3 Modification Design Using Test-Derived Model

Sometimes, it is impractical to construct a detailed and accurate mathematical model for a complex structure from theoretical considerations (even though it may be possible), and for these cases the construction of a model from tests can be very useful. A particular application here can be found in the evaluation of proposed structural modifications in an attempt to “tune” a structure’s dynamics. Tests on an existing structure, and especially those confined to the specific areas of interest, can be used to assess numerically the effect of making a series of alternative modifications (e.g., local changes of mass, stiffness, or damping) without the need to implement several variants of a basic idea on the actual structure. Parameter studies to

identify optimum values for certain key properties can be made by simulation, and only the final choice needs to be checked with further tests.

3.4 Troubleshooting

Lastly, there is a category of applications referred to as troubleshooting. In these cases, the ability to reconstruct and display the modes of vibration of an actual structure on the computer screen, to animate these in slow motion, and to inspect the details of this motion in critical areas of the structure can frequently provide a valuable insight into how the structure is actually moving. This insight, in the hands of a skilled engineer, can often be turned into an interpretation of what may well be very complex vibration behavior, and to explain why, even without the aid of a full mathematical model, thereby enabling the solution of a practical problem to be found.

4 PLANNING A MODAL TEST

4.1 Introduction

Before describing the techniques of data capture and analysis, we shall first discuss the overall concept and philosophy of the test procedure and identify those features critical to the effective and successful application of the process.

The essential components used in a modal test are well established (see Fig. 2). In addition to the items of specific hardware that are indicated on the schematic, there will generally be a software package used to manage the test, to collect and organize the various measurements, to process the measured data to reveal the required response functions, and, finally, to extract the underlying modal parameters from these response functions. The packages available for these activities are widely referred to as *modal analysis software*. For many of the items involved in planning the test, it is simply a question of selecting the unit with the most appropriate size or range. However, there are several other decisions to be made, mainly in respect of how to use the selected equipment, and these need an understanding of the underlying theory and philosophy of the method.

The basic concept of a modal test is that of measuring the response to a controlled and known

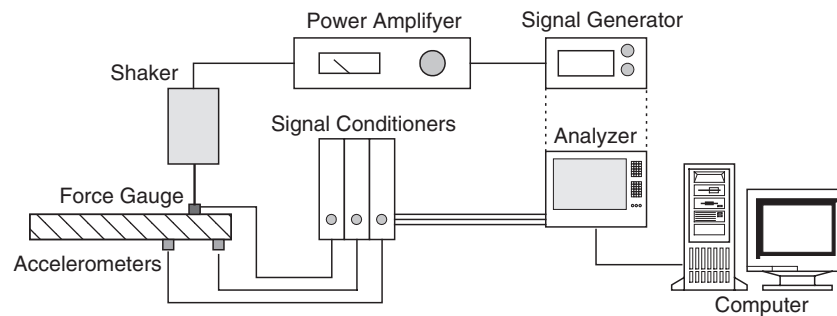

Figure 2 Basic components for a modal test setup.

applied excitation, and a number of key decisions in respect of this feature must be made early in the planning phase. The nature of the excitation device must be selected with care, as must the type of excitation signal that will be used to drive the structure. Another important decision is where the excitation(s) should be applied for maximum effect. Here we meet the common issue that the answers depend to some extent on the specific purpose and application of the test in question. In some applications, such as model validation, the accurate measurement of certain modes is more important than for others. In this case, a choice of excitation position can be made so as to maximize the visibility of the important modes and to suppress the response in unimportant ones. This will ensure a uniform accuracy of extracted modal data—a feature that is not always achieved without careful selection of excitation position.

Likewise, the type and location of response transducers demand careful selection as the failure to measure at sufficient points may make the ensuing results difficult to interpret. On the one hand, it is necessary to ensure sufficient spatial density of measurement points in order to be able to discriminate between two modes of similar form, while on the other, it is wasteful and unhelpful to so overspecify the number of response points that time is wasted in testing without matching benefits from the results. At the same time, the use of inappropriate transducers can bring about major systematic distortions in the resulting measurements—such as can be caused by mass-loading effects—for which it may be impossible to compensate in the post-measurement processing of the measured data.

4.2 Test Planning and Virtual Testing

It is common practice nowadays for guidance on the test planning phase to be available from the modal analysis software used for the processing of measured data and extraction of the target modal parameters. When a modal test is undertaken for the purpose of validating a preexisting mathematical model, it is often possible to use the very model that is to be validated to help design the test itself. Specifically, with a model of the structure, extended to include the proposed test setup, it is possible and very effective to rehearse the planned tests in a numerical simulation, long before any hardware is produced or test program decided.

Careful planning of modal tests can pay handsome dividends by greatly reducing the possibility (a) of missing certain key data and/or (b) of overestimating the quantity of data that is required. With such information provided for the tester by this “virtual testing” concept, a near-optimal test schedule can be drawn up that delivers the best results possible in the time available for the test.

5 MEASUREMENT TECHNIQUES

5.1 Introduction

In this section we summarize the main stages in the measurement phase of a modal test. There is

extensive literature addressing this important phase, and the reader is directed to Refs. 5 and 6, which include significant documents of a standards nature. Reference 5 is a multipart International Organization for Standardization (ISO) document on some of the fundamental measurement processes involved in modal testing, while Ref. 6 is a handbook of best practices that was prepared in the early 1990s under the auspices of the Dynamic Testing Agency (DTA) in the United Kingdom. In addition to these references, there are literally thousands of studies published in the past 40 years, many of which can be found or referenced in the conference proceedings of IMAC⁷ and ISMA⁸. It should also be noted here that a number of the other chapters in this handbook deal in more detail with some of the individual items of equipment that are referred to below.

5.2 Excitation Devices

There are several different types of device that are routinely used to generate the excitation necessary to conduct a modal test. These include:

- Electrodynamic exciters
- Electrohydraulic exciters
- Mechanical (rotating mass) devices
- Impactors and hammers
- Magnetic excitation
- Step-release devices
- Acoustic excitation

Each of these has particular advantages and drawbacks, the choice in each test usually being based on a balance between the degree of potential interference that attachment of the exciter causes on the structure against the ease of making accurate measurements of the actual forces exerted on the test structure. The noncontacting, and thus nonintrusive, excitation mechanisms carry with them a significant difficulty in measuring the forces they exert on the structure. On the other hand, direct physical connection of the moving part of an electrodynamic or electrohydraulic exciter risks contributing a significant influence on the motion of the structure we seek to measure. It is common practice to make the connections between exciter and structure by means of inserting a push-rod or “stinger,” such as the one illustrated in Fig. 3. The primary role of this device is to transmit an excitation force along the drive axis of the shaker while at the same time avoiding simultaneous application of secondary forces in any of the five other axes through which the two devices are connected. This issue of secondary forces is one that can give rise to significant errors, and considerable care must be taken in preparing a modal test to ensure that such effects are minimized.

There are other problems that can arise as a result of interactions between the test structure and the exciter. A properly located force transducer can help to ensure that such problems do not lead to significant errors in the measured response properties.

Figure 3 Appropriate attachment of exciter to structure.

Finally, it is worth noting that there is growing interest in the use of “natural” excitation: excitation that comes from the environment in which the structure “operates” but that is such that it cannot be specifically identified or measured (referred to as “output-only modal analysis”).

5.3 Response Transducers

Another critical part of the measurement process is concerned with the effective transduction of the response levels, which must be measured at several points on the test structure. There are issues in selecting appropriate transducers that are centered around two main concerns:

1. The need to select sufficient measurement points so as to ensure adequate spatial coverage of the mode shapes and operation deflection shapes that are captured by the response transducers
2. The need to minimize the interference that the physical presence of transducers inevitably imposes on the test structure, thereby risking significant distortion of the vibration properties being measured

There are three primary transducer types in widespread use today:

1. Accelerometers (piezoelectric, piezoresistive, and other types)
2. Strain gauges
3. Laser-based devices, including scanning laser Doppler vibrometers and holography

Details of the actual devices available today can be found in other chapters of this handbook. However, it is worth noting here that when using accelerometers, or other similar attached transducers, and in situations

where it is required to obtain measurements at a large number of points, it is important to ensure that an efficient choice of measurement sites is made. The test planning methodology mentioned in Section 4.2 can also be applied to this critical aspect of the measurement process.

Some of the problems associated with the need to measure at many points on the structure can be avoided by using noncontacting optical “field” measurement methods and, in particular, the two laser-based techniques of scanning laser Doppler velocimetry (SLDV) and holography. The main limitation of response measurement using laser-based methods is the need for a clear line of sight to each of the degrees of freedom of interest. Nevertheless, these methods offer considerable advantages.

5.4 Excitation Signals for Modal Testing

A third issue to be addressed in planning a modal test is the question of what type of excitation signal will be used. There are essentially four categories of excitation signal in widespread use and, again, each has particular advantages and drawbacks. These are (i) sinusoidal, (ii) periodic, (iii) transient, and (iv) random and are illustrated schematically in Fig. 4.

The first, and traditional, excitation signal is the simple sine wave. For this approach, the structure is excited at a specific frequency for long enough to capture measurements of the excitation force and all the response transducers before moving on (stepping rather than sweeping as in the past) to the next frequency where the same procedure is repeated, and so on until sufficient frequency points have been addressed. This approach tends to be slow, although it has a sometimes overlooked advantage that it allows the specific selection of each individual measurement frequency and does not demand, as do other methods, measurements at a fixed series of equally spaced frequencies spanning a chosen range. In practice, this means that it is possible to choose frequency steps that are close together near regions of resonance or antiresonance but that are more widely spaced in frequency regions where the response functions change more slowly (see Fig. 5). The sinusoidal excitation method is widely accepted as being the most precise and the most appropriate for cases where nonlinear behavior is expected or encountered.

The second commonly used excitation signal is periodic excitation. In this case, the structure is excited simultaneously at all the frequencies where measurements are required. In most current implementations where a discrete Fourier transform (DFT) type of spectral analysis procedure is used to analyze the measured data, a typical periodic excitation signal will contain components of every frequency in the analyzer spectrum. Typically, that might mean frequency components at 1-Hz intervals between 1 and 1600 Hz, for example. Such a signal has a clear advantage over the single-frequency sinusoidal excitation in that since all frequency points are measured simultaneously, the time required to acquire the necessary data to construct a response function should be much shorter than

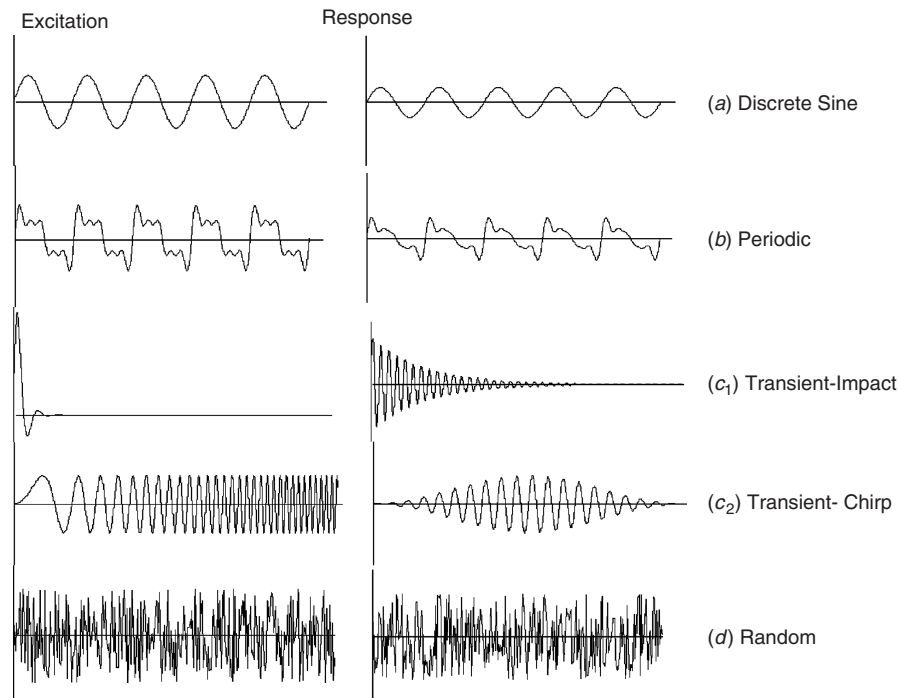

Figure 4 Common signal types used for modal tests: (a) sinusoidal, (b) periodic, (c) transient, and (d) random.

Figure 5 Typical FRF measurement using sinusoidal excitation signal.

a method in which the frequency points are measured sequentially. However, the comparison is not quite so simple as this statement implies because, in practice, with a sinusoidal excitation many of the frequency points that find themselves away from regions of resonance or antiresonance might not need to be measured in a discrete sine test, and because of the relatively low signal strengths on each of the individual frequency components of the periodic signal, it is often necessary

to average for a reasonable period of time in order to filter out background noise.

The third common excitation type is transient. This comes in a number of specific types, with the impulse generated by an impact hammer or similar device being the most widely encountered. However, there are other transient signals that can be used with an attached shaker and these include: (a) controlled sine pulse, (b) single chirp, and (c) burst random and other continuous signals.

To avoid problems associated with the signal processing in each of these transient excitation signals (see Chapters 40, 42, and 46), it is necessary to arrange the test conditions such that not only has the excitation signal died away at the end of the finite measurement period but so also has the response signal. While transient excitation signals are deterministic, in the same way that sinusoidal and periodic signals are, the exact spectral transformation of such an aperiodic signal is a Fourier integral rather than the Fourier series, which is what is obtained when using a DFT analysis (as is almost always the case in modal testing). As a result of using the DFT analysis process, only an approximate indication of the structure's response function is obtained when using transient excitation signals. Considerable care must be exercised to keep these approximations to an acceptable level.

The fourth excitation signal, which has been used for a considerable time, is random excitation. This is the only nondeterministic signal used in modal

testing and in cases where a truly random excitation signal is used, such as is generated in a random noise generator, the signal processing and subsequent analysis necessary to obtain the required response functions for the structure's behavior involve more assumptions and need more care than is required for the deterministic signals. It is necessary to average both excitation and response signals for a considerable period of time to obtain statistically reliable results. Even then, there is only a finite probability of being acceptably close to the right answer, and this residual uncertainty can only be reduced by measuring data for longer and longer periods. As in the case of transient signals, this type of signal processing using the DFT incurs additional approximations to the resulting parameters and, in the case of random excitation, it is generally necessary to apply a windowing correction compensation procedure to all the measured signals to minimize the errors incurred. Figure 6 shows a typical frequency response function measured with a random excitation signal, including an indicator of quality (the coherence) on the response function.

The reader is referred to specialist texts for more detailed explanation and guidance in dealing with the problems associated with the measurement of the data required to carry out an experimental modal analysis. However, this section should serve to alert the modal tester to the more significant sources of potential errors that can generally be avoided by expert use of standard equipment.

6 PARAMETER EXTRACTION TECHNIQUES

6.1 Introduction

At the end of the measurement phase, it is customary to have acquired a set of measured response functions. The actual measurements taken are time histories of excitation forces and responses, but it is normal practice to convert these either to FRFs, for a

Figure 6 Typical FRF measurement using multi-frequency excitation signal and DFT spectral analysis.

frequency-domain description, or to impulse response functions (IRFs), for those cases where a time-domain description is required. Nowadays, the vast majority of practical applications of experimental modal analysis provide the measured data in the form of FRFs. The next step in the process is to extract from these response functions a set of parameters that describe the underlying modal properties of the test structure. This is done using the basic theoretical relationship between the response model and the modal model and is usually carried out by fitting a theoretical curve of the correct form (but with initially unknown coefficient values) to the measured responses. Although application of these parameter extraction methods is increasingly a routine process, there are a number of subtleties and complexities that mean that it is appropriate to have a good understanding of the theoretical basis and assumptions on which the various algorithms are based. These will be outlined in this section.

6.2 Essential Principles

The basic theoretical expression for a typical FRF described in terms of modal parameters (response model from modal model) is given in Eq. (8). It is seen that the typical response function can be expressed by a summation of components from all of the modes of the structure, and that the relative importance or weighting of each modal component is related to the proximity of its natural frequency to the frequency at which the response function is defined. Figure 7a shows the essential construction of a frequency response function in terms of individual modal components. It can also be seen that within a narrow range of frequency in the immediate vicinity of each resonance, the frequency response function can be approximated by a single modal component plus two terms that represent approximately the effect of all the modes with lower and higher natural frequencies [Eq. (9) and Fig. 7b]. This expression is often further simplified to that shown in Eq. (10) with a single constant term to represent the combined effect of all other modes. Although this expression is not exact, it can be seen that if interest is confined to a very narrow range of frequencies around the natural frequency of one particular mode, it becomes a very good approximation and represents the underlying principle whereby the parameters of one mode can be extracted from analysis of a response function measured in the vicinity of the natural frequency of that mode:

$$H_{jk}(\omega) = \sum \frac{r A_{jk}}{\omega_r^2 - \omega^2 + 2i\omega\omega_r\zeta_r} \quad (8)$$

$$r A_{jk} = (\phi_{rj})(\phi_{rk})$$

$$H_{jk}(\omega)_{\omega_1 < \omega < \omega_2} \simeq \sum \frac{r A_{jk}}{\omega_r^2 - \omega^2 + 2i\omega\omega_r\zeta_r} - B_{jk}/\omega^2 + C_{jk} \quad (9)$$

$$H_{jk}(\omega)_{\omega \sim \omega_s} \simeq \frac{s A_{jk}}{\omega_s^2 - \omega^2 + 2i\omega\omega_s\zeta_s} + s D_{jk} \quad (10)$$

(a)

(b)

(c)

Figure 7 FRF curves in different formats: (a) construction of general FRF curve, (b) approximate FRF in vicinity of resonance, and (c) Nyquist plot of FRF in vicinity of resonance.

6.3 Single-Mode (SDOF) Modal Analysis

The FRF in the immediate vicinity of a natural frequency can also be examined in other presentation formats such as the Nyquist diagram in Fig. 7c. It can be seen that in this case the response function traces out a near-circular arc and that the underlying circle is displaced from the origin of the plot by a quantity, D . The properties of the circle contain the parameters of the mode in question, and the displacement of the circle from the origin represents the contribution of all the other modes and from a simple curve-fit analysis of a few response function data points, we can start to compile a table of modal parameters for the particular response function in question.

6.4 Multi-mode (MDOF) Modal Analysis

The previously described method is the most simple of those available, but with the widespread availability of extensive computation capacity, it is possible to undertake more ambitious and more accurate curve-fitting procedures. The first extension of the above approach, and one that relaxes any assumptions about single-mode dominance, is one in which the data points are fitted to a formula that contains not one but several modal components (so-called “MDOF” modal analysis). This is essentially a general curve-fitting process and there are several algorithms available for carrying it out. The result yields a table of best estimates of the modal parameters for the identified modes, plus any residual terms necessary to take account of the existence of other modes with natural frequencies outside the measured range—the so-called modal truncation effects. In this context, “best” is in the sense of a minimum least-squares error between the measured data points and corresponding points on the curve regenerated using the identified parameters themselves. Figure 8 illustrates the results from an MDOF modal analysis of a single FRF, clearly showing the importance of including the residual terms to account for the out-of-range modes.

6.5 Global Modal Analysis

Further extension of the generality in curve-fitting FRFs is possible by undertaking simultaneous analysis of several response functions relating to different points on the structure. If we have, say, a dozen frequency response functions that all share the same excitation point, k , but relate response levels at different points, such as $j = 1, 2, 3, \dots$ (i.e., the FRFs in a single column of the FRF matrix), then there are certain features of which we can take advantage to speed up the parameter extraction process by analyzing all curves simultaneously. The modal constants would be different for each of the response functions, but the natural frequencies and damping factors must be the same because they relate to the same mode. Advantage can be taken of this feature by arranging a simultaneous analysis of all the response functions over a common frequency range and by building in the constraint that the eigenvalue part of the solution (natural frequency plus damping factor) has a unique

Figure 8 Regenerated FRF curves and original measured data for single-FRF analyses: (a) MDOF curve fit, (b) MDOF omitting residual terms.

value and does not vary from curve to curve. Indeed, even greater generality is possible by using FRFs from several columns, or different excitations, in this analysis.

It is possible to use the MDOF analysis approach so that we can construct a table of all the eigenvalues for the modes that have been included in the measurement and as many of the individual elements from the eigenvectors as are covered by the set of measured response functions (in general, each FRF yields information on one DOF). These latter approaches to the parameter extraction task are usually referred to as “global” methods as they seek to provide a total solution to the modal model that is required and can be extended to include any set of FRFs in the “polyreference” version.

6.6 Parameter Extraction Algorithms

A large number of different numerical algorithms exist for the parameter extraction process. As we have described, they can be categorized into:

- One mode, one FRF (the SDOF method)
- One mode, several FRFs (global SDOF method)

- Several modes, one FRF (MDOF method)
- Several modes, several FRFs (global or polyreference MDOF method)

All these algorithms are based on the same underlying theoretical model, at least as far as the mass and stiffness are concerned. There are some variations as regards damping, reflecting the fact that, in reality, “damping” covers a wide range of different phenomena and mechanisms and is only ever represented approximately. However, each method attaches a different weighting to the measured data points with the result that each tends to give slightly different results to the others for real measured data that do not conform perfectly to the underlying linear assumptions. The reasons for this include:

- Slight nonlinearity in the structure
- Changes that can occur in the test structure’s properties during the test

A significant factor in this respect results from the fact that many of the limitations to response function measurement are particularly significant near resonances, and these effects are most sensitive to the differences that exist between the different algorithms.

6.7 Construction of Mathematical Model from Modal Parameters

The preceding sections have been concerned with the extraction of individual modal parameters from measured responses. At the conclusion of such a process we shall have a table containing values for natural frequencies, damping factors, and individual eigenvector (mode shape) elements. These data comprise a modal model for the structure that has been tested, and an example of a typical mode shape from one such model, measured on an automotive panel, is shown in Fig. 9. In principle, the data contained in this model should be capable of reconstructing or regenerating the response functions that were measured and used to determine the modal properties. Ideally, they should also be capable of constructing a spatial model consisting of mass stiffness matrices. However, this transformation of information from one type of model to another is hampered by two practical effects.

The first of these issues is the obvious one in that the essential data that have been used to construct the model are *inaccurate*: They contain errors of measurement or of structural behavior. These errors, although small, will be propagated through a conversion from response to modal models, and back, and so will affect the quality of any subsequent model. Sometimes, the propagation has a deleterious effect in that small errors in the original data can escalate to large ones in the model.

The second limitation is more critical and stems from the fact that the data that have been measured, and the modal model that has been constructed from those measurements, are *incomplete*. It is clearly not possible to measure all the modes of a structure, nor

Figure 9 Mode shape derived by modal analysis of scanning later measurements on an automobile panel.

to measure the mode shapes at all the degrees of freedom on a structure. As a result, a modal model that is constructed from a conventional modal test will include only a small fraction of the full properties. Examination of the formulas that link the modal model to the spatial model and the response model [see Eqs. (4), (5), and (6)] show that these are predicated on the assumption that each of those models is complete and that it contains information at all the degrees of freedom and for all the modes. This is clearly not possible for a practical structure and, as a result, although it is possible to construct a limited modal model from a set of measured frequency response functions, it is not possible to create a spatial model.

6.8 Determining the Number of Necessary Modes

The number of modes required in a mathematical model for a test structure depends strongly on the application of that model. If the model has been constructed to validate predictions from a theoretical model, and these predictions comprise a set of natural frequencies and mode shapes in a given frequency range, then a very useful application can be undertaken with only a limited set of modes. If, however, the application that is sought involves the need to use the model for calculating the response of the structure, then any restriction in the number of modes included in the model can present a significant limitation. To calculate accurately the response of a structure at a given frequency, it is

necessary to include components in the response from all the modes of vibration, including those whose natural frequencies are some distance from the frequency of the vibration of interest. The consequences of omitting the effect of modes “outside the range” of the modal test is demonstrated graphically in Fig. 8.

As a result of these considerations, it is as important to take due account of the number and choice of modes that are included in the model as it is to ensure that all the data and analyses provide accurate values for their respective parameters.

CHAPTER 48

MACHINERY CONDITION MONITORING

Robert B. Randall

School of Mechanical and Manufacturing Engineering
The University of New South Wales
Sydney, New South Wales, Australia

1 INTRODUCTION

The vibrations measured externally on operating machines contain much information as to their condition, as machines in normal condition have a characteristic *vibration signature*, while most faults change this signature in a well-defined way. Thus, vibration analysis is a way of getting information from the inside of operating machines without having to shut them down. Machine vibrations are measured in two fundamentally different ways: relative displacement of a shaft in its bearings using so-called proximity probes and absolute motion of the casing, usually at the bearings, using absolute motion transducers. The former must normally be designed into the machines and are typically used on high-speed turbomachines with fluid film bearings. They are used for permanent monitoring of relatively simple parameters such as peak-to-peak relative displacement and shaft orbits (in the bearing) and are primarily used to protect valuable and critical machines by shutting them down in the event of excessive vibration levels being developed. Only in a limited number of situations can long-term predictions be made, basically because incipient faults often show up first at high frequencies, to which the relative displacement measurements are not sensitive. This chapter is mainly concerned with measurements made with accelerometers (giving a signal proportional to vibration acceleration, possibly integrated to velocity), but proximity probe and other measurements (e.g., torsional vibration) are discussed where appropriate.

2 MACHINE VIBRATION SOURCES AND DIAGNOSTIC TECHNIQUES

2.1 Related to Shaft Speed

A number of faults manifest themselves at a frequency corresponding to the speed of the shaft. Among these are unbalance, misalignment, and cracked shaft, and the problem is to distinguish between them. In general, misalignment tends to produce a stronger second harmonic of shaft speed and more axial motion, but the nonlinearity of components in the system (such as fluid film bearings) can distort the response to unbalance force, leading to higher harmonics, and moment unbalance gives rocking motions with axial components, so the division is not clear. Flexible couplings are often introduced to mitigate the effects of misalignment but introduce their own characteristics into the vibrations. Reference 1 describes how many types of couplings, for example, Hooke's joints and gear couplings, give even harmonics of shaft speed, primarily second order. It also shows how the

harmonics generated are related to coupling design. For constant unbalance distribution and alignment, cracks in shafts give changes at the low harmonics of shaft speed, though these may be more evident as a change in phase angle (relative to the phase of a once-per-revolution tacho signal) rather than in amplitude. Sophisticated rotor dynamic models are now being made of the most critical machines, and these provide the best possibilities for distinguishing between unbalance, misalignment, and shaft cracks, at least with the machine running at speed and load. Cracks can be detected during rundowns, not so much by a change in critical speed as by an increased response when harmonics of shaft speed pass through the critical speed(s).^{2,3}

Other faults show up at subsynchronous frequencies, such as *oil whirl*, usually between 40 and 48% of shaft speed, caused by a resonant wave in the fluid film bearing. This can sometimes be confused with *hysteresis whirl*, due to hysteretic friction between components on the rotor. The friction forces are such that a self-excited whirl is generated on passing through the shaft critical speed and remains at this frequency as the shaft speed increases.⁴ Since many machines run at about twice their first critical speed, this can sometimes be confused (and perhaps even merged) with oil whirl. When oil whirl combines with resonant shaft response, it is sometimes called *oil whip*. Exact subharmonics (e.g., one-half or one-third) can result from *parametric excitation*, variations in stiffness due to looseness, "rubs," and the like and can be distinguished by their exact subharmonic nature. Sudden changes in stiffness also increase the number of superharmonics, even in the absence of subharmonics.

A finely tunable harmonic/sideband cursor is useful to distinguish between exact and approximate subharmonics and between harmonics of shaft speed and mains frequency (see Section 2.2). Phase relationships between the two ends of a machine can distinguish between lateral and rocking motion. A phase difference of 90° between the horizontal and vertical transducer signals at one location indicates circular or elliptical orbits, while if they are in phase, motion must be along a straight line. Proximity probes are useful for fluid film bearings for a number of reasons as mentioned earlier. Determination of the position of the shaft in its bearing (and thus the point of minimum oil film thickness) helps to distinguish between unbalance, misalignment, and shaft cracks. The shape of the orbit, and whether it is precessing forward, or backward can help to distinguish between the different types of whirl,

for example, dry friction tends to excite backward precessing modes.⁴ A useful source of information of the applications of proximity probes is the magazine *Orbit* produced by Bently Nevada Corporation.⁵

2.2 Electrical Machines

Electrical machines such as alternating current (ac) motors and generators generate vibrations due to electrical as well as mechanical forces.⁶ Stator faults tend to give increases at twice mains frequency (line frequency in the United States), as this is the rate at which the poles of the rotating magnetic field are passing a fixed point (the anomaly) on the stator. For two-pole synchronous machines, this is the same as twice shaft speed, and thus it can be difficult to distinguish between a stator fault and misalignment. However, the electrical forces are strongly dependent on the load, and varying the load may allow the two effects to be separated. Switching off the power and tracking the second harmonic as it runs down in speed allows complete separation. For induction motors⁶ the situation is easier in that the shaft speed is less than synchronous, and fast Fourier transform (FFT) zoom analysis allows separation of the harmonics of shaft speed from those of mains frequency. Figure 1 shows an example of a fault on the rotor of a four-pole induction motor (in the United States where the mains frequency is 60 Hz). The main effect is at the shaft speed (corresponding to the rate of rotation of the fault), but it can be distinguished from mechanical unbalance by virtue of the strong modulation sidebands that are clearly in evidence. The sideband cursor shows that these are spaced at 1.0 Hz, which is the number of poles times the slip frequency of 0.25 Hz (synchronous speed 30 Hz minus shaft speed 29.75 Hz). As explained in Ref. 6 this is the frequency at which the poles of the rotating field pass a given point (the anomaly) on the rotor.

2.3 Gears

Gears represent a typical component where the wide frequency range of accelerometers is needed. The basic vibration generating mechanism in gears is the

transmission error (TE), which can be understood as the relative torsional vibration of the two gears, corrected for the gear ratio. The TE results from a combination of geometric errors of the tooth profiles, and deflections due to tooth loading. Thus, even a gear with perfect involute profiles will have some TE under load, and it is important to make comparisons of gear vibration spectra under the same load to obtain information about changes in condition.

Gear vibration signals are dominated by two main types of phenomena⁷:

- Effects that are the same for each meshing tooth pair, such as the tooth deflection under load and the uniformly distributed part of initial machining errors and/or wear. These manifest themselves at the tooth-meshing frequency and its harmonics. Since there is a pure rolling action at the pitch circle, and sliding on either side, tooth wear tends to occur in two patches on each tooth, and thus wear is often first seen as an increase in the second harmonic of the tooth-meshing frequency.
- Variations between the teeth, which can be localized or distributed more uniformly around the gears. These manifest themselves at other harmonics of the gear rotational speeds for the gear on which they are located. Localized faults such as cracks and spalls tend to give a wide dispersion of harmonics and sidebands throughout the spectrum, whereas more slowly changing faults such as nonuniform wear tend to give stronger harmonics grouped around zero frequency and as sidebands around the harmonics of tooth-mesh frequency.

Since even with faults, the same geometric shapes always mesh in the same way, the signals produced by gears are basically deterministic, at least as long as the teeth remain in contact.

Most gear diagnostic techniques thus use time synchronous averaging (TSA) as a precursor to isolate

Figure 1 Example of a rotor fault on an induction motor, showing modulation sidebands around the shaft speed component of 29.75 Hz (spacing 1 Hz).

the vibrations from each individual gear. TSA is useful to extract that part of a signal that is periodic with the same period as a trigger signal, for example, a once-per-revolution tacho signal from a given shaft.⁸ In practice, it is done by averaging together a series of signal segments each corresponding to one period of the synchronizing signal. To correct phase errors, it is necessary to first resample the signal to have a fixed number of samples per period, with the first lined up with the synchronizing signal. Such processing is called *order tracking* because the frequency axis can then be better scaled in harmonic orders rather than hertz. Order tracking can be done using a shaft encoder on a particular shaft to control the sampling clock, or by using a phase-locked loop tracking the tacho signal to generate a fixed number of sampling pulses per period of the locked frequency. Most modern analysis systems achieve the same effect by digitally resampling the signal at constant shaft phase increments, based on analysis of the tacho or shaft encoder signal.⁹ This has the advantage that signals are available with both temporal and angular sampling, and transformation can be made between the two at any stage. Special techniques have been developed to get the averaged signature of sun and planet gears in a planetary gearbox, eliminating the effects of the varying distance of the planets to an external measurement point by capturing the signature of each tooth as it passes the measurement point.¹⁰

A general problem is to detect local faults on a gear once the averaged signature has been obtained. The effects of these are often obscured by the normal tooth-meshing pattern, so various techniques have been developed to remove the latter. The traditional way is to remove all harmonics of the tooth-meshing frequency in the frequency domain, inverse transforming back to the time domain to evaluate the result. The kurtosis (see Chapter 46) is a useful parameter for characterizing the severity of the residual

signal because it is a sort of normalized crest factor, and the local peak values are much greater than the background noise. A new method has recently been developed to obtain the residual signal using linear prediction.¹¹ An autoregressive (AR) parametric model is developed for the signal from an undamaged section of a gear using linear prediction, and when a damaged section of the gear enters the mesh, the actual value of the signal departs dramatically from the linearly predicted value, and the “error” gives a measure of the local change. Figure 2 compares the results of the two techniques for a typical case.

In some cases the presence of a local fault is not very clear, even after TSA, and a method has been developed to reveal a local fault by amplitude and phase demodulation of the tooth-meshing frequency of the signal using Hilbert transform techniques.¹² Figure 3 shows that the phase of the result revealed a crack long before it became evident in the amplitude of the signal. Attempts are currently being made to distinguish between the effects of cracks and spalls since the former would tend to give much more rapid failure.¹³ Since spalls are a geometric error, while cracks give a change in stiffness, the symptoms of the latter are more load sensitive. In Chapter 88 an example is given of the detection of a local fault at light load.

Modulations of the gear-mesh signal give rise to sidebands around the gear-mesh harmonics and can often be revealed and quantified using the cepstrum, as described in Ref. 14. Another application of the cepstrum is in detecting echoes, and, in particular, it can be shown that an inverted echo makes all components in the cepstrum negative. Reference 15 shows how this can be used to locate spalls since these give rise to a negative echo in the acceleration signal as the mating tooth enters and leaves the spall.

Figure 2 Enhancement of fault indications using AR modeling vs. harmonic removal: (a) residual signal (kurtosis, 11.14) obtained using linear prediction and (b) residual signal obtained (kurtosis, 3.03) by canceling harmonics of tooth-mesh frequency. (From Ref. 11. Reprinted by permission.)

2.4 Bearings

The discussion here is limited largely to rolling element bearings since with fluid film bearings in principle there should not be any metal-to-metal contact and consequent wear. There have been very few studies of detecting the wear of fluid film bearings from their vibration signals, but the operational faults that could give rise to such wear can be monitored by the techniques described in the section on shaft-related vibrations. This is one area where the use of oil analysis can aid vibration analysis, as bearing metals are quite distinctive in their chemical composition.

Figure 4 shows typical acceleration signals produced by localized faults in the various components of a rolling element bearing and the corresponding envelope signals produced by amplitude demodulation. It can be shown that analysis of the envelope signals gives more diagnostic information than analysis of the raw signals. The diagram illustrates that as the rolling elements strike a local fault on the outer or inner race, a shock is introduced that excites high-frequency resonances of the whole structure between the bearing and the response transducer. The same happens when a fault on a rolling element strikes either the inner or outer race. As explained in Ref. 16, the series of broadband bursts excited by the shocks is further modulated in amplitude by two factors:

- The strength of the bursts depends on the load borne by the rolling element(s), and this can be modulated by the rate at which the fault is passing through the load zone.
- Where the fault is moving, the transfer function of the transmission path varies with respect to the fixed positions of response transducers.

Figure 4 Typical signals and envelope signals from local faults in rolling element bearings.

Figure 4 illustrates typical modulation patterns for unidirectional load on the bearing; shaft speed for inner race faults, and cage speed for rolling element faults. The formulas for the various frequencies shown in Fig. 4 are as follows:

Ballpass frequency, outer race:

$$\text{BPFO} = \frac{nf_r}{2} \left\{ 1 - \frac{d}{D} \cos \phi \right\} \quad (1)$$

Ballpass frequency, inner race:

$$\text{BPFI} = \frac{nf_r}{2} \left\{ 1 + \frac{d}{D} \cos \phi \right\} \quad (2)$$

Fundamental train frequency (cage speed):

$$\text{FTF} = \frac{f_r}{2} \left\{ 1 - \frac{d}{D} \cos \phi \right\} \quad (3)$$

Ballspin frequency:

$$\text{BSF} = \frac{Df_r}{2d} \left\{ 1 - \left(\frac{d}{D} \cos \phi \right)^2 \right\} \quad (4)$$

where f_r is the shaft speed, n is the number of rolling elements, and ϕ is the angle of the load from the radial

plane. Note that the BSF is the frequency with which the fault strikes the same race (inner or outer), so that in general there are two shocks per basic period. Thus the even harmonics of BSF are often dominant.

These are, however, the kinematic frequencies assuming no slip, and in actual fact there must virtually always be some slip for the following reason. The angle ϕ varies with the position of each rolling element in the bearing, as the ratio of local radial to axial load changes, and thus each rolling element has a different effective rolling diameter and is trying to roll at a different speed. The cage ensures that the mean speed of all rolling elements is the same, by causing some random slip. This is typically of the order of 1 to 2%. This random slip, while small, does give a fundamental change in the character of the signal and is the reason why envelope analysis extracts diagnostic information not available from frequency analyses of the raw signal. It means that bearing signals can be considered as cyclostationary (see Chapter 46). This also allows bearing signals to be separated from gear signals¹⁷ with which they are often mixed, as discussed below.

A very powerful technique for diagnosing bearing faults is using *envelope analysis*, as mentioned above. It can be shown that the spectrum of the raw signals (as depicted in Fig. 4) contains little diagnostic information as it is dominated by the high-frequency resonances excited and has only a small response at the actual characteristic frequencies given by Eqs. (1)–(4). Because of the small random fluctuation of the repetition frequencies, the higher harmonics of the bearing fault frequencies typically smear together in the vicinity of the resonance frequencies, giving the appearance of a noise spectrum. However, if the signal is bandpass filtered in a frequency band where there is a maximum (decibel) change in the spectrum caused

by the bearing fault, and then amplitude demodulated, the spectrum of the resulting envelope contains low harmonics of the fault frequencies (and any modulation sidebands), which are not appreciably smeared.

Figure 5 shows the envelope spectrum from measurements made on a gear test rig with and without a rolling element fault in a bearing. The major increases in the raw spectrum as a result of the fault were between 10 and 20 kHz, and there was negligible spectrum change below 8 kHz, even though the BSF was only 26 Hz. Figure 5 shows the spectrum of the square of the envelope, this having been shown in Ref. 18 to give better results than the spectrum of the envelope. This envelope spectrum is typical of a rolling element fault since it is dominated by harmonics of BSF (with the even harmonics more prominent) and with sidebands and low harmonics spaced at the cage frequency (the rate of passage of the fault through the load zone). Where the bearing signal is masked by discrete frequencies (often due to gears), it is possible to remove them before demodulation. This was originally achieved¹⁸ by self-adaptive noise cancellation (SANC), making use of the fact that the random slip in the bearing signals makes their correlation length short in comparison with the deterministic gear signals. A later development called discrete/random separation (DRS), described in Ref. 19, achieves the same thing but much more efficiently since both the generation of the separation filter and its application by fast convolution are achieved using FFT methods. Figure 6 shows how DRS has been used to separate a faulty bearing signal from a normal gear vibration signal by which it was completely masked.

Occasionally, gear and bearing signals are combined multiplicatively rather than additively (when gear-mesh signals are modulated by the faulty bearing

Figure 5 Spectrum of the squared envelope signal obtained by demodulating the signal in the band between 15 and 20 kHz. The dotted line at the base shows the envelope spectrum with no bearing fault.

Figure 6 Separation of (additive) gear and bearing signals using DRS: (a) combined signal, (b) deterministic part (gear signal), and (c) stochastic (cyclostationary) part (bearing signal).

signal). The gear signal and first-order cyclostationary (periodic) part of the bearing signal can first be removed using DRS, after which the second-order cyclostationary part can reveal bearing faults and distinguish them from gear faults even though at the gear rotational frequency.¹⁷ A second-order cyclostationary component at shaft speed, for example, would indicate a bearing inner race fault, at the same time separating this random component from stationary random noise.

2.5 Reciprocating Machines

Reciprocating machines, such as diesel engines and reciprocating compressors, also produce vibrations with both periodic and cyclostationary components. The latter are, for example, associated with combustion, which occurs every basic cycle, but not identically each time. Signals from reciprocating machines have a different character from those of simple rotating machines, as they consist of a series of impulsive events (combustion, piston slap, valves opening and closing, etc.), and so the most effective analysis techniques must take into account variations in both frequency and time (or crank angle). It is thus common

to use some form of time–frequency analysis to analyze the signals of reciprocating machines. This can be as simple as an STFT (short-time Fourier transform) analysis, where a window is moved along the record in overlapping steps and the spectrum determined for each window position. The result will be found to be more repeatable if the STFT diagram is averaged over several cycles (power spectrum average making it insensitive to phase variations). However, the STFT suffers from limitations in resolution given by the Heisenberg uncertainty principle, where the product of frequency and time resolutions is a constant. Obtaining a better time resolution (by a shorter window) gives a poorer frequency resolution and vice versa. The Wigner–Ville distribution (WVD) appears to give better simultaneous time–frequency resolution but suffers from nonphysical interference terms that are difficult to distinguish from the physically meaningful components. A range of smoothed versions have been developed²⁰ to reduce the interference while still retaining better simultaneous resolution, but these are all very onerous computationally. A relatively new development, which is very promising for internal combustion (IC) engine diagnostics, makes use

of the Wigner–Ville (or instantaneous) spectrum, an ensemble-averaged version of the WVD, which is ideal for second-order cyclostationary signals.

If the periodic part of the signal is first removed (e.g., by DRS), the interference terms in each realization of the WVD come with random phase and are canceled by averaging, leaving a time–frequency diagram with excellent resolution. Figure 7 compares the Wigner–Ville spectrum with the WVD for a typical diesel engine cycle.

Another diagnostic technique that has received some attention in the literature is the recovery of cylinder pressure signals from external measurements, of head/block acceleration, and/or crankshaft torsional vibration,^{22–24} but generally applicable results have still not been achieved.

However, crankshaft torsional vibration, obtained by frequency demodulation of a shaft encoder signal, is a simple and very powerful tool for detecting misfires on an individual cylinder.²⁵ Figure 8 shows an example from a six-cylinder spark ignition engine, where there was no spark on one cylinder. The shaft encoder signal used was from a proximity probe detecting the passage of teeth on the ring gear. The first harmonic of the tooth passage frequency was first phase demodulated by Hilbert transform techniques, and the phase signal differentiated to frequency (angular velocity) by multiplying by $j\omega$ in the frequency domain. Performing the differentiation this way allows a simultaneous bandpass filtration, the lower limiting frequency being just less than the basic cycle frequency, and the upper limiting frequency

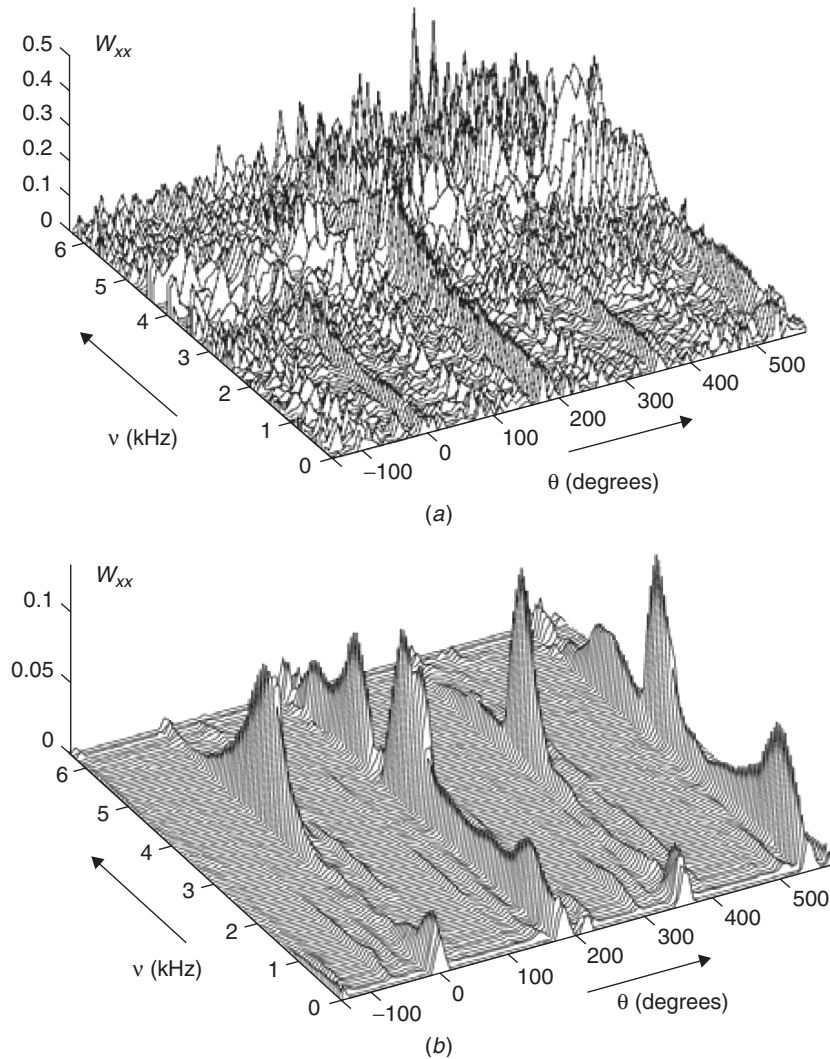

Figure 7 (a) WVD over one cycle of a diesel engine and (b) WVS averaged over 120 cycles. (From Ref.21.)

Figure 8 Angular velocity (instantaneous crankshaft speed) for a spark ignition engine with a misfire on cylinder 6.

chosen to avoid amplifying high-frequency noise. The torsional vibration can alternatively be determined by using a high-frequency clock (e.g., 20 MHz) to time the intervals between the pulses, and this has the advantage that the same number of samples is obtained per cycle, independent of the speed. For some very localized faults it may be an advantage to further differentiate the signal to angular acceleration.

3 VIBRATION MONITORING SYSTEMS

The type of vibration monitoring system to be employed depends on the criticality of the machine being monitored and the economic driving factors. There is a basic division between permanent monitoring with fixed transducers and intermittent monitoring with portable equipment and offline analysis. The major economic benefits of condition monitoring usually come from predicting incipient faults well in advance, allowing repairs to be planned, spare parts to be acquired, and in particular avoiding losses in production, this often being a much more important economic factor than the damage to an individual machine.

Since an advance warning of several months is often required to minimize production loss, and it is now often possible using signal processing techniques to obtain this much lead time, intermittent monitoring is usually the most economical approach for the vast majority of machines. This is typically done using data collectors into which "route maps" can be downloaded, describing the measurement points on all machines to be monitored in a single excursion into the plant. Reference spectra and other data pertaining to each point can be downloaded at the same time as the route map, and standard analysis procedures can be implemented semiautomatically, such as spectrum comparisons and specific diagnostic procedures once a fault has been detected. Simple procedures can be done directly in the field, but data is usually stored and transferred back to a central computer,

allowing more detailed analysis to be done later if required. Monitoring intervals are typically weekly to monthly, depending on the anticipated leadtime and the criticality of the machine.

A small number of very critical machines often have permanently mounted transducers that can detect sudden changes in condition and initiate shutdown. Even though this automatically gives some loss in production, this may be minimal compared with what would result from an undetected catastrophic failure of the machine. Permanent monitoring is often performed with proximity probes, possibly supplemented with accelerometers, and is usually based on measuring simple parameters that allow rapid shutdown. Of course, if permanently mounted accelerometers are in place, detailed analysis can also be done, and would often be done at intervals of one day or so, giving more security than intermittent measurements at weekly or monthly intervals, and maximizing the lead-time after detection of change.

Whether for permanent or intermittent monitoring, accelerometers should typically be mounted on the bearings, where the dynamic loads are transmitted from internal rotating components to the casing. It is often sufficient to measure in one radial direction (vertical or horizontal) on radial bearings, and in the axial direction at thrust bearings, typically only at one end of a machine. The mounting point should be the same each time, usually by having a permanent mounting stud, and should be sufficiently rigid to give a repeatable frequency range up to at least 10 kHz. For intermittent monitoring, magnet mounting can be used if sufficiently rigid to give the required frequency range (e.g., rare-earth magnets) and if mounting points are sufficiently well defined (e.g., permanent magnet mounting pads).

4 FAULT DETECTION AND TREND ANALYSIS

As mentioned above, the use of accelerometers, possibly with integration to velocity, allows the measurement of signals with a frequency range of more than three decades, for example, 5 Hz to 5 kHz or 20 Hz to 20 kHz, with very good dynamic range, and such a range can be necessary to detect the full range of possible faults. These can extend down to 40% of shaft speed (e.g., oil whirl) up to the 400th harmonic of shaft speed (e.g., harmonics of gear-mesh and blade-pass frequencies). Rolling element bearings often have fault indications at frequencies of the order of 1000 or more times the shaft speed. Criteria exist for vibration severity, such as the International Organization for Standardization (ISO) Standard 2372 (developed from the German recommendation VDI-2056), and the so-called General Machinery Criterion Chart,²⁶ which was developed from the earlier Rathbone and Yates charts. These all represent equal velocity criteria, for a wide range of machine sizes and speeds, and can be expressed in terms of root-mean-square (rms) levels covering the frequency range 10 to 1000 Hz (where the only reason for the upper frequency limitation is the fact that much of the data on which they were based was obtained using velocity probes with that

frequency range). Velocity best represents vibration severity because all vibrations represent an alternation between potential energy proportional to the square of strain and kinetic energy proportional to the square of velocity. Since design stress is largely independent of size and speed, vibration velocity tends to be fairly uniform over a range of machines and over a wide frequency range. However, an accelerometer with electronic integrator is the best velocity transducer, as it gives a much wider frequency and dynamic range in velocity than a direct velocity probe.

Even though the two standards mentioned above have different criteria for different machines, both are in agreement that equal changes in severity are represented by equal changes on a log amplitude scale and that a change of 20 dB (amplitude ratio 10:1) is serious. It can also be inferred that a change of 6 to 8 dB (ratio 2 to 2.5) is significant. Rather than using absolute criteria, a strong argument can be made for detecting faults based on the change from the normal levels at each measurement point, with 6 and 20 dB representing significant and serious changes, respectively. The use of velocity means that there is a better chance than otherwise that changes at any frequency will affect the rms levels, but it is still evident that monitoring of frequency spectra, rather than overall levels, will have a better chance of detecting changes at whatever frequency they should occur.

To compare digitized frequency spectra, it is common to make some kind of smeared "envelope" of the reference spectrum, to avoid problems with small speed changes, and the large changes in sample values along the steep flanks of discrete frequency peaks. A simple and very efficient way of doing this is to use constant percentage bandwidth (CPB) spectra, rather than FFT spectra, since their resolution is uniform on a logarithmic axis, and small speed changes can be compensated by a lateral shift. At the same time a CPB spectrum can cover a wide frequency range with a relatively small number of spectrum values. Figure 9 shows the application of this technique to signals from an auxiliary gearbox on a gas-turbine-driven oil pump.²⁷ It shows the comparison of a 4% bandwidth spectrum (180 values over three decades in frequency) with a mask formed from the original reference spectrum, and the resulting spectrum of exceedances. One of these exceeds 20 dB, but had stabilized, and in fact the machine was allowed to run under close supervision for a further 4 months before it was shut down for repair.

The positive spectrum changes detected by this procedure also provide a good way of trending changes in a condition as discussed in Ref. 28. Since equal changes in severity represent equal changes on a logarithmic amplitude axis, it is logical to plot the changes in decibel values, and a linear trend of decibel values would indicate a normal rate of change. If the severity of the fault feeds back on the rate of change of fault development, it might be better to fit an exponential curve to the dB values, to predict the time before they exceed a certain threshold, such as

Figure 9 (Upper) Comparison of new spectrum with mask, velocity dB re 1×10^{-6} m/s and (lower) decibel difference spectrum.

20-dB change. It can be checked whether a linear or exponential trend gives the best fit to the data. It can be misleading to fit other curves, such as polynomials, to the data, as they are dangerous to use for extrapolation. The best prognostic methods use a failure model for the particular type of failure that has been diagnosed and fit the measured data to that model. This is advisable for cases such as rolling element bearings, where the symptoms may change in discrete steps as piecewise spalls develop (undetected below-surface cracking).

CHAPTER 49

WAVELET ANALYSIS OF VIBRATION SIGNALS

David E. Newland
Engineering Department
Cambridge University
Cambridge, United Kingdom

1 INTRODUCTION

A wavelet is a short wave. Wavelet analysis is concerned with the decomposition of the time histories of signals into short waves. Any waveform may be used for the decomposition provided that it is localized at a particular time (or position). For convenience in this chapter, time is taken to be the independent variable, so that localization results in concentration at a particular time, although any physical variable can be used. Wavelet analysis provides a valuable method of generating time–frequency (scale) maps of vibration signals. These allow the changing character of nonstationary vibration signals to be studied. Wavelets are becoming increasingly used in the analysis and solution of noise and vibration problems and in practical health monitoring of machinery.

2 WAVELET TRANSFORMS

2.1 Wavelet Coefficients

If $w(t)$ is the function of time t that describes a wavelet, and $x(t)$ is the signal being studied, then the wavelet coefficient $a_w(t)$ is defined by the correlation equation

$$a_w(t) = \int_{-\infty}^{\infty} x(\theta)w(t - \theta) d\theta \quad (1)$$

In effect $a_w(t)$ is a correlation function. It provides information about the structure of $x(t)$ and how it correlates with the shape of a wavelet $w(t)$ positioned at time t . When $x(t)$ correlates with $w(t)$, then $a_w(t)$ will be large; when they do not correlate, $a_w(t)$ will be small. Of course, more information is obtained if the correlation process is repeated with a different wavelet function, $w_1(t)$. Later in this chapter, the symbol x is used for the independent variable, instead of t , according to the usual notation of wavelet analysis.

2.2 Properties of Wavelets

Wavelets are essentially local functions so that $w(t) \rightarrow 0$ when $|t| \rightarrow \infty$. Therefore, in practical terms, the integral in (1) needs to extend over only a limited range of θ , and $a_w(t)$ gives information about $x(\theta)$ in the vicinity of $x(\theta = t)$.

That is how wavelet analysis differs from Fourier analysis. Fourier transforms are calculated by the same equation (1) when the wavelet function $w(t)$ is replaced by a harmonic function. In that sense, Fourier analysis may be thought of as an extreme case of wavelet analysis. In Fourier analysis, the requirement

that the wavelet should be a local function is ignored, and it is replaced by a wave that goes on forever.

Much of the theory of wavelet analysis is about *self-similar wavelets* (which are wavelets of the same shape but different length scales) spaced at discrete intervals along the time axis. It turns out that, just as a periodic signal may be represented by the (infinite) sum of its harmonics in Fourier analysis, so a transient signal may be represented by the (infinite) sum of the (weighted) amplitudes of its component wavelets. The component wavelets all belong to a doubly infinite set of self-similar wavelets: Each different wavelet is different both in scale and in position on the time axis.

2.3 Comparison with the Short-Time Fourier Transform

Because Fourier coefficients are obtained by averaging over the full length of a signal, Fourier analysis provides no information about how frequency composition may be changing with time. To obtain *local* frequency data, a record must be divided into sections and each segment analyzed separately. The short-time Fourier transform (STFT) does this and is essential if the changing frequency composition of a transient signal is to be examined. Frequency coefficients computed by the STFT depend on the length and time (or position) of the short record that the calculation process assumes is one period of a periodic signal. Results computed by the STFT depend on how a record is subdivided, and making a good choice may be crucial. But the difficulty remains that infinitely long harmonic functions are being used to decompose a transient signal. It is usually better to employ a set of short functions as the basis for decomposing transient records. Wavelets are such short functions.

2.4 Discrete Wavelet Transforms

The practical embodiment of wavelet transforms, as for the Fourier transform, requires a discrete calculation using sampled values of the continuous record $x(t)$. Just as the continuous Fourier transform is replaced by the discrete Fourier transform, so the continuous wavelet transform is replaced by the discrete wavelet transform.

If $X(j)$, $j = 1$ to N , are sampled values of the record $x(t)$, and $A(k)$, $k = 1$ to N , are sampled values of its wavelet transform (which are arranged in a logical order that takes account of the scale and position of the wavelet), then

$$A = WX \quad (2)$$

where W is an $N \times N$ square matrix whose elements are determined by the chosen wavelet. Unless W is singular, the X numbers can always be regained from the A numbers, but, if W is an orthogonal matrix, it is not necessary to compute the inverse of W since $W^{-1} = W^T$, the transpose of W .

2.5 Orthogonal Wavelet Transforms

When reconstruction is needed, orthogonality of W is extremely important, so, for applications involving signal processing in which reconstruction is necessary, there has been tremendous interest in developing the theory of orthogonal wavelets. Even for orthogonal wavelets, efficient numerical algorithms are essential because numerical efficiency is extremely important. Any wavelet decomposition algorithm has to be judged against the fast Fourier transform (FFT) of Cooley and Tukey,¹ which for an N point sequence requires of the order $N \log_2 N$ multiplications instead of N^2 multiplications. Therefore, attention has focused on orthogonal wavelets with fast numerical algorithms.

3 DILATION WAVELETS

The first orthogonal wavelets to be developed for practical numerical computation, called dilation wavelets, arose from the pioneering work of Daubechies.²⁻⁵ They depend on the theory of dilation equations, which form a special class of difference equation. There is an efficient numerical algorithm due to Mallat⁶ for computing dilation wavelet transforms, and there are now various software toolboxes that implement his discrete dilation wavelet transform and its inverse. Dilation wavelets are compact in the time domain, which means that each wavelet has a definite beginning and a definite ending, and they are zero outside these limits. In the frequency domain they are not so restricted and necessarily cover an infinite frequency range, although being concentrated about a center frequency. A typical dilation wavelet is shown in Fig. 1. It begins at $x = 0$ and finishes at $x = 3$.

3.1 Dilation Equations

With few exceptions, dilation wavelets cannot be expressed in functional form. Instead they are defined

Figure 1 Dilation wavelet with four coefficients, derived from the scaling function in Fig. 2. (From Ref. 7.)

by a dilation equation that has to be solved by iteration or recursion. There are two steps in the definition. Step 1 defines a scaling function $s(x)$ by an equation of the form

$$s(x) = c_0 s(2x) + c_1 s(2x - 1) + c_2 s(2x - 2) + c_3 s(2x - 3) \quad (3)$$

where the c 's are numerical (real) constants that may be either positive or negative. The wavelet $w(x)$, which corresponds to this scaling function, is defined by the corresponding equation

$$w(x) = -c_3 s(2x) + c_2 s(2x - 1) - c_1 s(2x - 2) + c_0 s(2x - 3) \quad (4)$$

The same coefficients are used, but in reverse order and with alternate terms having their signs reversed. These equations contain four coefficients, and they may be extended following the same pattern to include any even number of coefficients.

Apart from a few simple cases, Eq. (3) cannot be solved directly to find the scaling function $s(x)$. Instead a solution is found by iteration. Each new approximation $s_j(x)$ is computed from the previous approximation $s_{j-1}(x)$ by the iterative scheme

$$s_j(x) = c_0 s_{j-1}(2x) + c_1 s_{j-1}(2x - 1) + c_2 s_{j-1}(2x - 2) + c_3 s_{j-1}(2x - 3) \quad (5)$$

with the process being continued until $s_j(x)$ becomes indistinguishable from $s_{j-1}(x)$.

Figure 2 shows progressive stages in the generation of $s(x)$ according to Eq. (5). The process begins by taking the starting function $s_0(x)$ to be a box of length unity. This develops progressively into the shape that occupies the interval $0 \leq x < 3$. It has been computed for particular values of the coefficients $c_0 = 0.6830$, $c_1 = 1.1830$, $c_2 = 0.3170$, and $c_3 = -0.1830$,

Figure 2 Progressive stages in the generation of a dilation wavelet's scaling function, with four coefficients. (From Ref. 7.)

which have been chosen to ensure orthogonality and good convergence properties. Having found $s(x)$, the corresponding wavelet can be computed directly from Eq. (4), which leads to the shape shown in Fig. 1.

3.2 Mallat's Tree Algorithm

The iteration process represented in Eq. (5) can be carried out by a process of progressive multiplication. This was first implemented efficiently by Mallat⁶ in his tree algorithm. The full theory is mathematically complicated (for a summary see Refs. 7 and 16), but the concept of its operation can be described as follows.

Suppose that a vibration record of finite length has been sampled at equally spaced intervals to generate the input sequence $X(j)$, $j = 1$ to N , where $N = 2^n$. Its dilation wavelet transform is computed by progressively filtering this sequence with two digital filters. At each stage of filtering, the sequence length is reduced by half. A low-pass filter generates the half-length sequence $Y(k)$, $k = 1$ to $N/2$, and a high-pass filter generates the half-length sequence $Z(r)$, $r = 1$ to $N/2$, according to the formulas

$$\begin{aligned} Y(N/2) &= L(N/2, N)X(N) \quad \text{and} \quad Z(N/2) \\ &= H(N/2, N)X(N) \end{aligned} \quad (6)$$

where the orders of the matrices are as shown. The low-pass filter is represented by the matrix $L(N/2, N)$ and the high-pass filter by $H(N/2, N)$. This process is repeated with the Y vector (but not with the Z vector). The $Z(N/2)$ vector from Eq. (6) is retained. The $Y(N/2)$ vector is filtered by $L(N/2, N/4)$ and $H(N/2, N/4)$. After the second set of matrix multiplications, a second $Z(N/4)$ vector of length $N/4$ is kept, while the new $Y(N/4)$ vector is again subjected to a further decomposition. Eventually, the decomposition has continued until the orders of the final vectors are only one term each, and the transformation is complete.

The repeated matrix multiplication process defined by this process is a discrete computation of the correlation integral (1) where the wavelet function $w(t)$ is a dilation wavelet defined by the relevant coefficients c_0, c_1, c_2 , and so on. This is because each step in the iteration process defined by the dilation equation (5) is represented by a matrix multiplication by L . Since the matrices operate on a column vector X whose elements are the sampled values of $x(t)$ in (1), Mallat's tree algorithm gives a discrete approximation for the continuous integral in (1). This process is illustrated in Fig. 3 and the reverse transformation in Fig. 4.

4 MALVAR WAVELETS

A feature of the shape of the dilation wavelet in Fig. 1 is its irregular profile. Although dilation wavelets with more coefficients have a smoother shape, they do not have the familiar form of a smoothly windowed harmonic function. The use of windowed

Figure 3 Calculation of the dilation wavelet transform of an eight-term input sequence using $N = 4$ wavelet coefficients. (After Mallat.⁶)

Figure 4 Reverse calculation to find the inverse dilation wavelet transform of an eight-term sequence, using $N = 4$ wavelet coefficients. (After Mallat.⁶)

harmonic wavelets has been developed by Malvar⁸ and allows an arbitrarily chosen segment of a signal to be decomposed into a set of windowed harmonic functions. For each segment, the set of basis functions is exclusively either windowed cosine functions or windowed sine functions (Fig. 5).

For the frequency analysis of a measured signal this presents a problem. If there is a frequency component that is 90° out-of-phase with respect to Malvar's basis function at a given frequency, then the corresponding coefficient calculated by Eq. (1) will be very small. Without windowing, it would be zero. For example, if the basis functions are cosines, then a sine component at the frequency of one of the basis cosines will give an almost zero coefficient. Using the concept of *phase* from Fourier analysis, Malvar wavelets do not discriminate phase. For vibration analysis, this inability to represent phase is a disadvantage.

Figure 5 Malvar wavelet. (From Malvar⁸; this diagram after Meyer,⁹ Chapter 6.)

Another disadvantage is that the width of the window function, $l_j = \alpha_j - \alpha_{j+1}$ in Fig. 5, is the same for all frequency components. Therefore, localization is much less precise at high frequencies than it is at low frequencies. If we want to know within a few cycles where a particular frequency component occurs, the segmentation of a signal into finite lengths that are independent of frequency is not helpful. The STFT suffers from the same drawback. As for dilation wavelets, Malvar wavelets are compact in the time domain and infinite in the frequency domain.

5 MEYER WAVELETS

In Chapter 6 of his book, Meyer⁹ shows how he and Lemarié constructed an orthogonal set of time-scale wavelets by developing properties of Malvar's time-frequency wavelets. As Meyer pointed out, this is quite surprising because the Lemarié-Meyer wavelets constitute a "time-scale" algorithm, whereas the Malvar wavelets are a "time-frequency" algorithm. There is thus an incompatibility.

Instead of devising a wavelet by windowing a harmonic function by a tapered data window, as in Fig. 5, Meyer wavelets are defined in the frequency domain. By defining the wavelet's Fourier transform in a special way, it is possible to generate a complete set of orthogonal real wavelet functions of which an example is shown in Fig. 6. The magnitude of the defining Fourier transform is shown above, and the corresponding wavelet below. Because its Fourier transform is compact in the frequency domain, the wavelet itself extends over all time. Therefore Meyer's wavelets are less localized than dilation wavelets and

Figure 6 Typical Meyer wavelet (lower view) with the modulus of its Fourier transform (upper view). (From Daubechies,⁵ Chapter 4.)

Malvar wavelets, both of which have compact support in the time domain.

An advantage of Meyer's wavelets is that they can be computed by an algorithm using the FFT and mean Central Processing Unit (CPU) times may be comparable to, if not faster than, implementation of Mallat's pyramid algorithm for dilation wavelets. But for time-frequency analysis, Meyer wavelets have the same disadvantage in respect of phase discrimination as Malvar wavelets. Because all wavelets are self-similar, at each scale and each position, there is only one basis wavelet. This has the characteristic shape of the mother wavelet: it can be moved and it can be stretched or compressed, but its basic shape does not change. To recognize phase, at each level and each position, there have to be two wavelets with a 90° phase difference between them. This feature is provided by harmonic wavelets.

6 HARMONIC WAVELETS

Harmonic wavelets have their Fourier transform defined by

$$W_{m,n}(\omega) = 1/(n-m)(2\pi) \text{ for } m(2\pi) \leq \omega < n(2\pi) \\ = 0 \text{ elsewhere} \quad (7)$$

This is identically zero outside the band $m(2\pi)$ to $n(2\pi)$, where m and n are real and positive but not

necessarily integer. Inside this band it has constant magnitude, normalized to ensure that the enclosed area is unity. The corresponding wavelet function, obtained by taking the inverse Fourier transform of $W_{m,n}(\omega)$, is

$$w_{m,n}(x) = \{\exp(i n 2\pi x) - \exp(im 2\pi x)\} / i 2\pi(n - m)x \quad (8)$$

The subscripts m, n define the wavelets' frequency scale or "level" in the frequency band $m(2\pi)$ to $n(2\pi)$ where $n > m$. To form a complete set of wavelets, adjacent wavelet levels must have Fourier transforms whose frequency bands touch each other, so that all values of ω along the axis 0 to ∞ are included. Figure 7 shows the real and imaginary parts of $w(x)$ defined by Eq. (8) for the case when $m = 1, n = 2$. For harmonic wavelets, the (complex) wavelet amplitude $a_{m,n,k}$ is the amplitude of the wavelet at level m, n and position k . This means that $a_{m,n,k}$ is the amplitude of the wavelet at level m, n translated k steps at this level, which is $\Delta x = k/(n - m)$ along the x axis. Because of orthogonality, $a_{m,n,k}$ is given by

$$a_{m,n,k} = (n - m) \int_{-\infty}^{\infty} f(x) w_{m,n}^* \left(x - \frac{k}{n - m} \right) dx \quad (9)$$

where w^* denotes the complex conjugate of w .^{10,11}

Figure 7 (a) Real part and (b) imaginary part of the harmonic wavelet defined by (8) for the case when $m = 1, n = 2$. (From Newland,¹⁰ Fig. 2.)

A disadvantage of harmonic wavelets is that their rate of decay is low (proportional to x^{-1}) so that localization is not very precise. Their advantage is that since each wavelet is complex, with an even real part and an odd imaginary part (see Fig. 7), they can detect a harmonic frequency component whatever its phase. In other words, the ratio of the imaginary and real parts of harmonic wavelet coefficients provides a means of determining a position that interpolates between the locations of discrete wavelets.

7 DISCRETE HARMONIC WAVELET TRANSFORM

It can be shown (see, e.g., Newland,⁷ Chapter 17) that an algorithm for the computation of the $a_{m,n,k}$ coefficients can be devised using two applications of the FFT as illustrated in Figs. 8 and 9. This is drawn for the case when $n = 2m$ for all wavelet levels (with one exception, see below). The bandwidth of each wavelet level then doubles for each ascending level, so that the frequency scale increases in octaves.

There are two stages to the transform (Fig. 8). At stage 1, the FFT of the complete sequence $f(r), r = 0$ to 15, is computed to generate the (complex) sequence of Fourier coefficients $F(k), k = 0$ to 15. At stage 2, the $F(k)$ are partitioned into octave blocks as shown, and the IFFT of partitioned blocks is computed separately. This generates the (complex) harmonic wavelet coefficients $a(s), s = 0$ to 15. Symmetry of

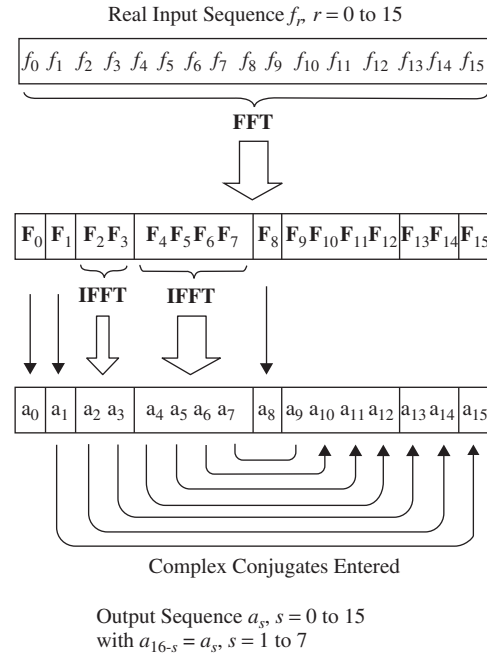

Figure 8 FFT algorithm to compute the harmonic wavelet transform for a real sequence of 16 terms for the case when $n = 2m$ for all wavelet levels. (From Newland,¹⁰ Fig. 6.)

Figure 9 FFT algorithm to compute the harmonic wavelet transform for a complex sequence of 16 terms, also for the case when $n = 2m$ for all wavelet levels. (From Newland,¹⁰ Fig. 7.)

the calculation ensures that $a(16 - s) = a^*(s)$, $s = 1$ to 7 (the asterisk again denotes complex conjugate).

To prevent vanishingly small bandwidths, m is not allowed to become less than unity except for a zero-frequency band $m = 0$ to $n = 1$. Thus the sequence of pairs (m, n) increase as (0,1), (1,2), (2,4), and so forth. The octave sequence is therefore complete except for a zero-frequency band $0 \leq \omega < 2\pi$.

A further major advantage of harmonic wavelets is that the speed of their computation is high. For a typical calculation, the discrete harmonic wavelet transform requires less than half the number of flops (floating point operations) of the dilation wavelet transform based on Mallat's algorithm with a dilation wavelet having 20 coefficients.¹⁰ This is important for large calculations that, for vibration calculations, often involve plotting time-frequency maps.

An additional property of the harmonic wavelet transform (HWT) is that it is not necessary to use octave blocks when calculating the IFFTs in Figs. 8 and 9. Instead, any convenient partitioning can be used. Furthermore, to obtain maximum discrimination in a time-frequency map, the blocks of coefficients used for the IFFTs can overlap each other. This oversampling does not generate any new data but

interpolates between data points to achieve a resulting improvement in discrimination. An example is given in Section 10.

8 MEAN-SQUARE WAVELET MAPS

For harmonic wavelets, wavelet level defines a finite frequency band; for dilation wavelets, wavelet level is a measure of the center frequency of a localized but infinite band of frequencies. Therefore, wavelet level is interchangeable with frequency for harmonic wavelets and a measure of predominant frequency for dilation wavelets.

The mean-square map depends on the result that the mean-square value can be represented as a summation of the magnitudes of the wavelet coefficients squared. For discrete dilation wavelets, the summation is

$$\frac{1}{2^n} \sum_{r=0}^{2^n-1} x_r^2 = a_0^2 + \sum_{j=0}^{n-1} \frac{1}{2^j} \sum_{k=0}^{2^j-1} a_{2^j+k}^2 \quad (10)$$

while, for harmonic wavelets, it is

$$\frac{1}{2^n} \sum_{r=0}^{2^n-1} x_r^2 = a_0^2 + \sum_{j=0}^{n-2} \frac{1}{2^j} \sum_{k=0}^{2^j-1} \left\{ |a_{2^j+k}|^2 + |a_{2^n-2^j-k}|^2 \right\} + a_{N/2}^2 \quad (11)$$

for the corresponding case when the frequency blocks cover octave bands.

If a three-dimensional graph is constructed with the moduli of wavelet amplitudes squared plotted on a base plane whose axes are wavelet level (represented by integer j) in one direction and position (represented by integer k) in the other (orthogonal) direction, the volume under the resulting surface can be normalized to be a measure of mean square. Where there are significant contributions to a signal's energy at particular frequencies and times, the mean-square surface will have localized peaks. Therefore, a contour plot of the mean-square surface will generate a two-dimensional map that illustrates the distribution of energy (i.e., mean-square value) over frequency and position.

8.1 Examples

Two examples are shown in Fig. 10. Wavelet maps of the same length of band-limited signal (shown) are drawn (a) for harmonic wavelets and (b) for dilation wavelets with $N = 20$ wavelet coefficients. The signal is represented by the discrete function x_r , $r = 0$ to 511, and the corresponding wavelet maps are shown immediately below this signal. Also, for clarification, mesh diagrams of the underlying shapes are drawn below each map. In the case of the harmonic wavelet map, it can be seen that the energy of the signal is confined to level 5 of the transform only. This is because x_r has been chosen to have a band-limited spectrum that falls within the frequency band of

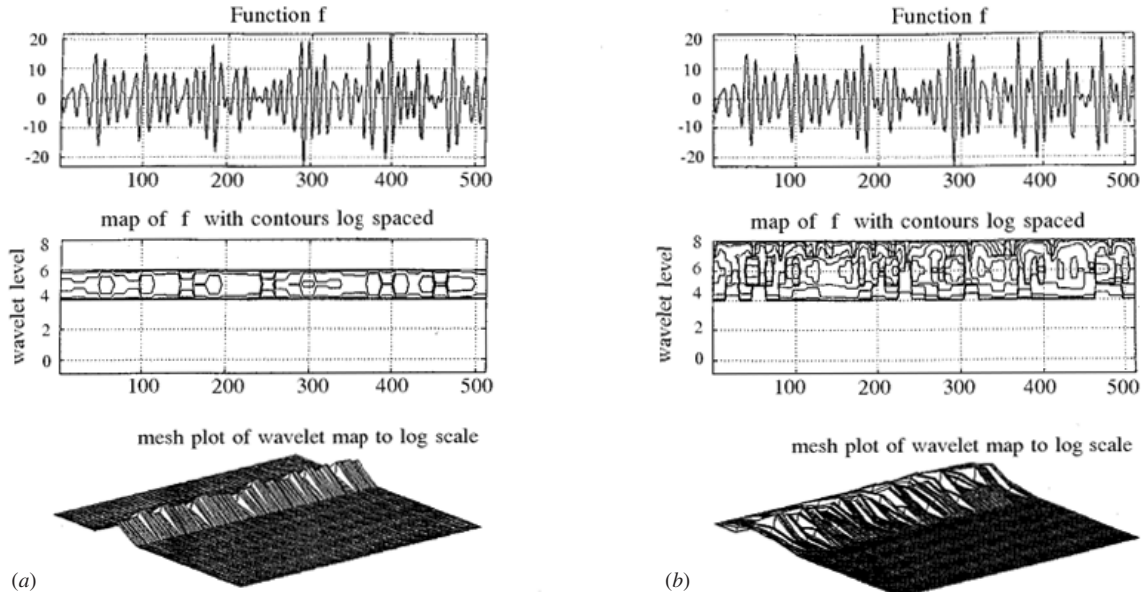

Figure 10 Discrete band-limited signal and its wavelet maps: (a) using harmonic wavelets and (b) using dilation wavelets with 20 coefficients. Mesh diagrams are drawn below each wavelet map. (From Newland.¹³)

level 5 of the harmonic wavelet transform. For dilation wavelets, the frequency spread is wider and is not band limited. Therefore, energy spreads over several levels of the dilation wavelet map as shown in Fig. 10b. The spacing of the contours and the vertical scale of the mesh diagrams in Fig. 10 are logarithmic, so the high peaks are relatively diminished in magnitude, but there is general correspondence between the location in time of the high peaks in x_r and the high peaks on the wavelet maps.

8.2 Applications

The use of mean-square wavelet maps to identify irregularities in otherwise smooth signals is shown in Figs. 11 and 12. The first shows a signal with a periodic local perturbation—almost invisible to the eye—and the corresponding harmonic wavelet map and mesh diagram with logarithmic scales. The identity and location of the peaks are now clearly visible. In Fig. 12, a harmonic signal has a single local higher frequency perturbation. The wavelet map and mesh diagram, again with logarithmic scales, allow this to be identified immediately. The identification of small, local perturbations on otherwise smoothly varying signals is one of the principal applications of wavelet analysis and offers considerable benefits in the field of vibration monitoring.

9 CONSTRUCTION OF TIME-FREQUENCY MAPS

9.1 Layout of Maps

The detailed layout of mean-square maps^{12,13} depends on which transform is used to compute the data that is

plotted. There are significant differences between the coordinate framework for HWT maps and STFT maps.

Begin with a (real) time history $f(t)$ sampled to generate the discrete time series $f(0)$ to $f(31)$. Let its harmonic wavelet representation be given by $a(0)$ to $a(31)$ and its short-time Fourier representation by $b(0)$ to $b(31)$. Provided that there has not yet been any windowing to destroy data, f 's can be perfectly reconstructed from either a 's or b 's. The information contained in the input signal $f(0)$ to $f(31)$ has just been shifted around to appear in different forms.

Figure 13 shows the grid base for a mean-square map computed by the HWT for an input signal with 32 terms. The grid framework has axes that represent time (or position) horizontally on the page and frequency (or wavenumber) vertically. When drawn in this way, the volume enclosed by a surface through the points plotted is numerically equal to the mean-square value of the input signal. There is a minor proviso. The wavelet coefficient at the Nyquist frequency, $a(N/2)$ (where for Fig. 13, $N = 32$), has been taken to be zero (which in all practical cases it must be), otherwise the map has to have an additional row.

Similar information is generated by the STFT and may be plotted on a time-frequency map that has similar properties to a mean-square wavelet map. However, the computational process is different. In essence it is the following: Start with an input sequence of 32 (real) terms, $f(r)$, $r = 0$ to 31. Divide this, for example, into 4 adjoining sequences of 8 terms each, $f(0)$ to $f(7)$, $f(8)$ to $f(15)$, $f(16)$ to $f(23)$, and $f(24)$ to $f(31)$. Compute the FFT of each 8-term series and call these $b(0)$ to $b(7)$, $b(8)$ to $b(15)$,

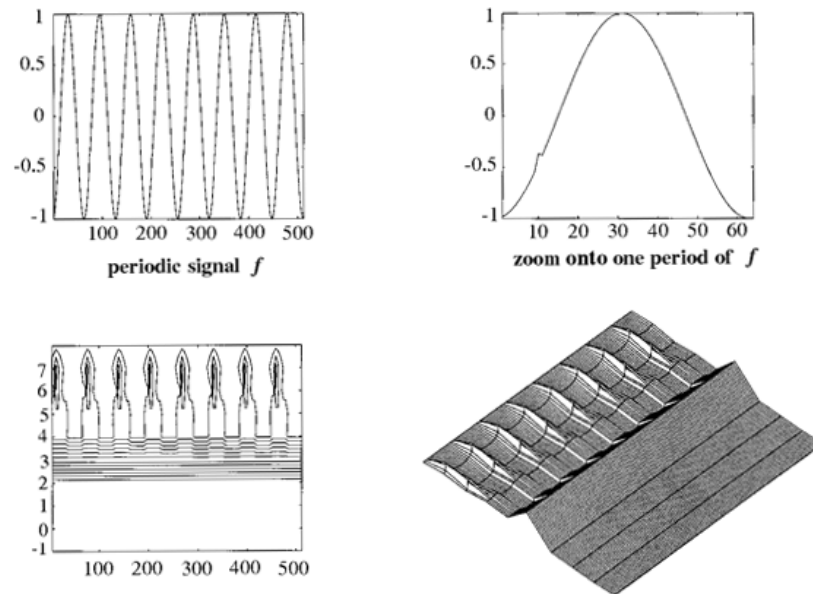

Figure 11 Discrete periodic signal f_r , $r = 0$ to 511, with its harmonic wavelet map and a corresponding mesh diagram of the map. The map contours are spaced logarithmically: Note how this accentuates the influence of the small local perturbations. (From Newland.¹³)

Figure 12 Discrete periodic signal with a local higher frequency perturbation. The harmonic wavelet map again allows this to be identified clearly. (From Newland.¹³)

Figure 13 Grid base for plotting a harmonic wavelet map for a 32-term sequence.

$b(16)$ to $b(23)$, and $b(24)$ to $b(31)$. Each of these 8-term series covers the full frequency range, with a middle term, for example, $b(4)$, being the Nyquist term. Hence $b(5) = b^*(3)$, $b(6) = b^*(2)$, and $b(7) = b^*(1)$ because of the symmetry of the FFT (see, e.g., Newland,⁷ Chapter 10). To obtain a time–frequency map, the square of the moduli of the short-time Fourier coefficients are plotted on the grid base shown in Fig. 14. Again because of Parseval’s theorem, the sum of the squares of the Fourier coefficients is equal to the mean square of the input signal. Hence the total volume under a rectilinear surface constructed on the baseboard in Fig. 14, with the ordinates shown, is numerically equal to 4 times the mean-square value of the 32-term series $f(0)$ to $f(31)$. The multiplier 4 arises because there are 4 subseries instead of one long series in the computation.

9.2 Lapped Transforms

Just as the f ’s may be processed in two different ways, they may also be processed more than once by the same basic method. Although this does not generate any new information, it allows the information that is there to be shown more clearly in a visual

Figure 14 Grid base for plotting a STFT map for a 32-term sequence.

way. For the STFT, the time history is broken into different blocks before computing the discrete Fourier transform of each. By choosing the blocks differently, different Fourier coefficients are computed for the same time series. When these are plotted on one time–frequency plane, more detail is added to the resulting time–frequency map. For the HWT, the frequency series is partitioned into different blocks before their inverse FFTs are computed according to Fig. 8. This again generates more points for the time–frequency surface and so adds discrimination (but not extra accuracy) to the resulting graphical output.

9.3 Windowed Transforms

In discrete spectral analysis, it is customary to window the input sequence before computing its FFT. The input data is weighted by a *window function*. The window tapers at its edges, reducing to zero at the two ends of the data. Its purpose is to ensure that the end of the input data can be wrapped around to make a seamless joint with its beginning. This is because the FFT computes the Fourier transform of a periodic signal, one period of which is the length of data being analyzed. To prevent the introduction of spurious Fourier coefficients arising from discontinuities where one period joins the next period, the application of a tapered window ensures that the beginning and end of each period meet smoothly.

Because data is destroyed by the windowing operation, this leads to a reduction in the statistical reliability of the Fourier coefficients in the case of random data. However, it is more important to minimize the introduction of spurious high-frequency Fourier coefficients arising from wrap around, which is inherent in the FFT calculation (see, e.g., Newland,⁷ Chapter 11), than to lose some statistical accuracy. The Hanning data widow (see, e.g., Bendat and Piersol¹⁵) of the form $[1 - \cos(2\pi t/T)]/2$ where T is the record length, is one of the simplest windows and is often used for practical calculations.

In the case of the HWT, it is also advantageous to window the blocks of frequency coefficients before their IFFT is computed (see Fig. 8). In this case the reason is different. A typical harmonic wavelet for an octave block of frequency coefficients is shown in Fig. 15. The rate of decay of the wavelet with time is proportional only to $1/t$. Decay is slow and localization is poor. When, before the IFFT computation is made, the octave block of frequency coefficients is windowed with a Gaussian function, the modified wavelet is shown in Fig. 16. Its rate of decay away from its center is much improved. Since the harmonic wavelet transform calculates the coefficients of the decomposition of the input signal into a family of harmonic wavelets, better localization on the time–frequency map is achieved if the localization of the wavelets is improved. Therefore, it is desirable to window the blocks of frequency coefficients when computing mean-square harmonic wavelet maps. Since the frequency coefficients are generally complex, windowing in the HWT computation is applied only to the moduli of the complex coefficients.

Windowing destroys the orthogonality of the harmonic wavelet transform. This is a disadvantage when reconstruction is required. However, by overlapping the transform blocks, excessive information is produced, N pieces of input data producing more than N pieces of output data. Only some of this data is needed to achieve exact reconstruction of the original signal. Therefore, it is possible to devise an algorithm for computing the windowed HWT of an input signal

that allows perfect reconstruction, provided that the Fourier blocks in Figs. 8 and 9 are overlapped.

10 EXAMPLE OF TIME–FREQUENCY ANALYSIS

10.1 Experimental Data

In the following example calculations, experimental data is used.¹⁴ This is the response of a long, thin steel beam when subjected to a transverse impulsive impact. The beam's transverse acceleration response close to the point of impact is shown in Fig. 17. This is in the form of a 1024-term series. The data sampling frequency was 4096 Hz. By using a soft-tipped impulse hammer, it was possible to ensure that significant aliasing did not occur as frequencies approaching the Nyquist frequency of 2048 Hz had been practically eliminated in the response.

Bending waves emanate from the point of loading and travel along the beam away from the impact until the end of the beam is reached. They are then reflected and return to reach the measuring point, before this process repeats itself. The recorded acceleration should therefore show bursts of waves passing the measuring point as reflections continue until the vibrational energy is dissipated by damping.

10.2 STFT Time–Frequency Map

A time–frequency map constructed by applying the STFT is shown in Fig. 18. The input record has been divided into overlapping blocks of 128 terms each, with each new data block advanced 8 points with

Figure 15 Modulus of a harmonic wavelet whose frequency band covers one octave (*upper view*) with the real part (*lower left*) and imaginary part (*lower right*) shown separately. The wavelet was computed for a 4096-term sequence $F(k) = 0, k = 1$ to 4096 except for $F(k) = 1$ for $k = 129$ to 256.

Figure 16 The same as Fig. 15 except that the moduli of the frequency coefficients $F(k)$ in the octave band have been windowed by a Gaussian weighting function with its “standard deviation” set to one-fourth of an octave.

Figure 17 Measured impulse response data; sequence length 1024. The time scale is horizontal, the frequency scale vertical.

respect to the last. Before computing the FFT of each block, the block is windowed by a Hanning weighting function of the form $[1 - \cos(2\pi j/128)]/2$, $j = 0$ to 127. The first block starts at the beginning of the 1024-term input data sequence, and there are 113 blocks with the last one finishing at the end of the input data. The presence of curved hills and valleys in Fig. 18 arises for the reason already explained. At any chosen frequency (on the vertical axis in Fig. 18), by drawing a horizontal line on the map, it can be seen that the mean-square response rises and falls as waves arrive from successive reflections and then pass

the measuring point. Knowing the dimensions of the beam and the position of the measuring point relative to the two ends, it is possible to estimate the group velocity of the waves and to determine its dependency on frequency from the time–frequency map.

10.3 HWT Time–Frequency Map

A second time–frequency map, for the same input data in Fig. 17 but computed by the HWT, is shown in Fig. 19. This has been computed by first calculating the FFT of the complete data sequence $f(r)$, $r = 0$ to 1023, as in Fig. 8. Then the IFFTs of

Figure 18 Time–frequency map from the data shown in Fig. 17 when computed by the STFT. The time index is plotted horizontally, the frequency index vertically. Short data sequence length 128; each short segment advanced 8 points from the last; short data blocks windowed by a Hanning weighting function.

Figure 19 Time–frequency map for the data in Fig. 17 when computed by the HWT. As for Fig. 18, the time index is plotted horizontally, and the frequency index vertically. Frequency block length 128; each frequency block advanced 8 points from the last; frequency blocks windowed by a Gaussian weighting function with a “standard deviation” of $1/16$ of each block’s bandwidth.

overlapping blocks of 128 frequency coefficients have been calculated to generate the wavelet coefficients. Each new frequency block has been moved 8 places with respect to the last so that 49 separate frequency blocks are possible without overlapping either end of the frequency scale (the Nyquist frequency is term 513). These have been plotted to generate the map in Fig. 19. Each block of 128 frequency coefficients has been weighted by a window of the form $\exp[-(j-64)^2/2\sigma^2]$, $j = 0$ to 127, where in Fig. 19 $\sigma = 8$, before its IFFT has been computed. Because each block is 128 terms long, it generates 128 wavelet coefficients corresponding to the wavelets whose centers are uniformly distributed along the time axis. Hence the horizontal axis in Fig. 19 runs from 1 to 128 (whereas that in Fig. 18 runs from 1 to 113 because 113 STFTs were computed). In this case the time base covers the full length of the input record. The

frequency scale is not the same as Fig. 18, however. This is because the middle frequency, of the first block of frequency coefficients is $64/512$ of the Nyquist frequency, and the middle frequency of the last of the 49 frequency blocks is $64/512$ below the Nyquist frequency. For the two graphs as plotted, Figs. 18 and 19, the frequency scales are therefore different. This difference may be reduced by using different block sizes but has been retained here to illustrate the difference between the two methods.

10.4 Comments on These Results

Both the STFT method and the HWT method process the input time history to generate data for a time–frequency map. Comparable results can be achieved with each, but it can be shown that the wavelet method usually has advantages in speed of computation. The best choice of wavelet for a given

application is not obvious. But no method can overcome the fundamental uncertainty principle that to improve accuracy in frequency, it is necessary to reduce accuracy in time, and vice versa. This uncertainty does not allow a precise frequency to be identified from a short record length. If the standard deviation of a spectral estimate is to be equal to its predicted (mean) value, then frequency bandwidth B and record length T are related by the well-known equation (see, e.g., Newland,⁷ Chapter 9) $BT = 1$. That is an unavoidable limitation that always applies.

CHAPTER 50

USE OF NEAR-FIELD ACOUSTICAL HOLOGRAPHY IN NOISE AND VIBRATION MEASUREMENTS

Earl G. Williams
Naval Research Laboratory
Washington, DC

1 INTRODUCTION

Since the first use of near-field acoustical holography (NAH) in 1980, there has been a rapid increase of research, development, and marketing with practical applications finding their way into many varied noise and vibration problems in industry and transportation. For example, near-field acoustical holography has been used to study the interior noise in aircraft and automobiles and the vibration and radiation from surface ships and submarines, as well as the noise problems in commercial products used in the home. Near-field acoustical holography is remarkable in its ability to thoroughly characterize a radiating source. This is because of the fact that it provides from a single experiment a frequency spectrum reconstruction of the total power radiated, directivity patterns, normal surface velocity and intensity, and the acoustic intensity vectors in the volume from the surface of the source to the far field. The reconstructed surface intensity is used to locate the sources of noise on the radiating structure, thus providing a powerful diagnostic tool for noise control problems. This recovery of the velocity, intensity, radiated power, and far-field directivity is carried out completely in software not hardware. Thus, the need for expensive hardware, such as vibrometers, intensity probes, anechoic chambers, and reverberation rooms can be eliminated. Furthermore, a single experiment achieves all these goals, minimizing the measurement time needed to characterize a source as well as uncertainties due to disparate measurements made in different facilities at different times.

2 FIELD OVERVIEW

At the core of NAH is the measurement of a near-field hologram. This consists of a broadband measurement of the pressure on a two-dimensional hypothetical surface with a scanning microphone/hydrophone or an array of sensors. This hypothetical surface is located near to the source surface and generally conformal to it, when possible. Figure 1 shows the experimental setup for a planar NAH experiment, in this case used to study a plate vibrator. The hypothetical measurement surface is made up of an array of microphones, and the conformal source surface is the parallel plane tangent to the top surface of the plate. One needs to procure microphone arrays and/or robot-controlled scanners to implement the pressure hologram measurement. The NAH approach is very attractive due to the state-of-the-art development of microphone technology and advances toward miniaturization (e.g., MEMS microphones) along with reduction of per unit cost. Critical to the NAH approach is the software package that provides the reconstruction of the various acoustical quantities of interest. Some software packages are now available commercially, and the development of a software package is not trivial. Aimed at providing an in-depth understanding of NAH and the software behind it, much of this chapter is dedicated to providing a “cookbook” recipe for a planar NAH system, incorporating the newest advances to date. The planar approach is emphasized here because a large number of noise sources can be studied with it. Furthermore it forms the template of the other NAH approaches, highlighted below, that can handle noise sources that do not fit a planar approach.

Figure 1 Example of measurement of near field hologram using a microphone array shown above a rectangular plate vibrator.

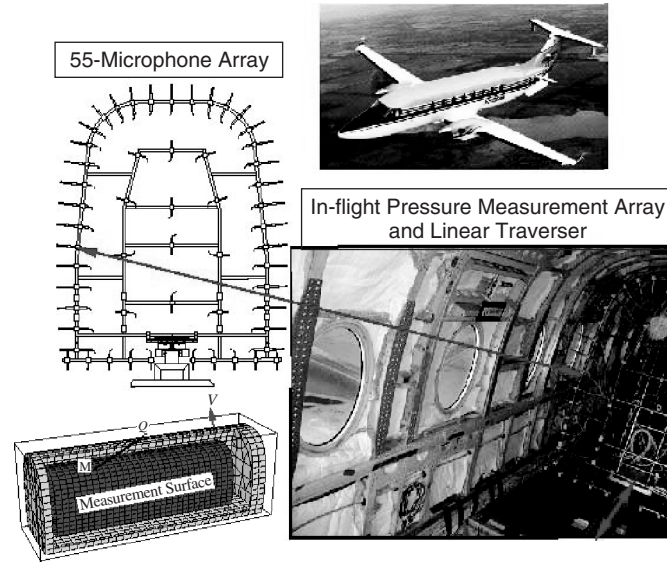

Figure 2 Experimental setup for measurement of interior hologram for IBEM using an array of 55 microphones. This array traversed the interior to produce a mailbox-like imaginary surface. Reconstruction surface was the fuselage and floor.

Also discussed is the most general form of NAH, which can be used to study sources of more complex surface geometry. This approach, which relies on the discretization of the Helmholtz integral equation, is called inverse boundary element methods (IBEM). Figure 2 shows an example of an experiment using IBEM to diagnose the interior noise on a Beechcraft airplane.¹ An array of 55 microphones in a vertical plane as shown in the figure was traversed through the cabin to acquire a broadband hologram on an imaginary mailbox-like surface as shown in the cutaway at the bottom left. IBEM was used to determine the pressure, normal velocity, and intensity on the fuselage surface and floor.

3 DEFINITION OF A NEAR-FIELD HOLOGRAM AND MEASUREMENT OF TIME-DOMAIN SIGNALS

Holography relies on the measurement of the phase relationship between all the sensor elements on the hologram surface. To put it another way, NAH requires acquisition of a spatially coherent sound field on an imaginary surface. For example, planar near-field acoustical holography requires instantaneous time snapshots of the pressure data $\bar{s}(x, y, z = z_h, t)$ over a planar measurement array (see Fig. 1) where $z = z_h$ represents the measurement plane. This requirement is satisfied by an array of microphones recording the sound field simultaneously. When a scanning microphone (or array) is used, then it is necessary to use stationary references recorded throughout the experiment. The reference signals may come from accelerometers attached to the source surface or microphones located close to the suspected radiation

sources. If this reference signal is denoted by $\bar{r}(t)$, the assumption that we are dealing with a linear system requires the following convolution relationship between the microphone signal and the reference (fixed in space) to be valid, where $h(x, y, z_h, \tau)$ is the transfer function of the medium:

$$\bar{s}(x, y, z_h, t) = \int_{-\infty}^{\infty} h(x, y, z_h, \tau) \bar{r}(t - \tau) d\tau \quad (1)$$

This convolution relation exists whether or not the measurement surface is a plane.

The NAH measurements have historically broken into two camps that follow the types of time series present. These time series are either random or deterministic. The first deals with sources that are random in nature (such as flow noise) and the signal processing associated with the creation of holograms uses random data analysis procedures² relying on correlation theory. The second camp deals with deterministic sources (such as a swept sine wave shaker excitation). In both cases it is assumed that the excitation is stationary in space, although moving sources can be handled when the motion is known a priori. The following outline describes the characteristics of these two signal processing approaches, and the mathematical details are detailed in the sections below the outline.

- Random excitation of structure
 - Random noise excitation
 - Cross power spectral analysis with ensemble averaging

- Application to in situ machines operating with in situ excitation
- Deterministic (nonrandom) excitation
 - Temporal pulses (chirps) or swept sine wave excitation
 - Time-domain signal averaging and temporal Fourier transforms
 - Excellent laboratory tool using point force excitations as well as in situ machines with strong harmonic spectral lines

The very earliest experiments in NAH used deterministic sources done using sine wave excitation^{3,4} to drive a structure of interest, such as a metal panel. Later the use of broadband pulses allowed for the acquisition of a wide band of frequencies from a single experiment.⁵ Although this approach is excellent for controlled laboratory experiments and in situ machines with strong tonals, many commercial noise sources are randomly excited and have vibrations that are not deterministic. The signal-processing front end is handled by a different approach,⁶ shown in the outline under random excitation. Important in this approach is the use of multiple references and its ability to deal with multiple excitation sources, often with the result that independent holograms are created for each source. This forms the essence of the STSF (special transformation of sound fields) procedure⁶ that uses a signal-conditioning approach to orthogonalize multiple references and provide holograms for each reference. When the references are statistically independent, then orthogonalization is not necessary and standard cross-correlation techniques are easily applied.² Other procedures for partially correlated references have been and continue to be developed.⁷ These signal-processing techniques are by no means trivial and with their careful application difficult noise sources can be tackled.

3.1 Deterministic Excitation

In the case of deterministic excitation, such as that created by a swept sine wave source, one can use the convolution theorem to obtain the frequency-domain unnormalized pressure $s(x, y, z_h, \omega)$ from Eq. (1):

$$s(x, y, z_h, \omega) = H(x, y, z_h, \omega)r(\omega) \quad (2)$$

where s , r , and H are the Fourier transforms of \bar{s} , \bar{r} , and h , respectively. The *normalized pressure* $p(x, y, z_h, \omega)$ representing the pressure coherent to the reference is determined from Eq. (2) and is defined as

$$p(x, y, z_h, \omega) \equiv s(x, y, z_h, \omega)/r(\omega) = H(x, y, z_h, \omega) \quad (3)$$

The normalized pressure is identical to the conjugate of the transfer function and has the units of pascals per unit of the reference. If the reference is a force signal, for example, the units are pascals per newton. The normalized pressure is used in Eq. (24) to compute the angular spectrum, which is the starting point for all of the NAH calculations.

The reference signal $\bar{r}(t)$ fixed in space is measured simultaneously with each position of the microphone array, as Eq. (2) requires. Generally, signal averaging is used to reduce the noise in the microphone measurements. The frequency domain signal is derived from Eq. (17) (MatLab call **fft**). Starting time at $t = 0$ using Eq. (10) where we redefine N as the number of time samples and q is replaced by j ($j = 0, 1, \dots, N - 1$) we have at each measurement location (x_q, y_r)

$$r(\omega_m) \approx \text{FFT}_j(\bar{r}(j\Delta t)) \quad (4)$$

$$s(x_q, y_r, 0, \omega_m) \approx \text{FFT}_j(\bar{s}(x_q, y_r, 0, j\Delta t)) \quad (5)$$

where FFT is fast Fourier transforms, and the first $N/2$ frequency bins ($f_m = \omega_m/2\pi$, and $j = 0$ corresponds to 0 Hz) are used and $\Delta f = 1/(N\Delta t)$.

3.2 Random Excitation

Again the objective is to determine the transfer function $H(x, y, z_h, \omega)$, which for random excitation, such as a shaker driven with a random time series, is determined using the auto and cross-spectral density functions between the reference and the microphone, denoted by $S_{rr}(\omega)$ and $S_{rs}(x, y, z_h, \omega)$, respectively. In this case Eq. (1) becomes

$$S_{rs}(x, y, z_h, \omega) = H(x, y, z_h, \omega)S_{rr}(\omega) \quad (6)$$

Thus the transfer function is

$$H(x, y, z_h, \omega) = S_{rs}(x, y, z_h, \omega)/S_{rr}(\omega) \quad (7)$$

Random processing forms the basis of the spatial transformation of sound fields (STSF)⁶ technique developed at Brüel and Kjaer. Once the front-end signal processing is accomplished, STSF uses NAH theory for the reconstruction of the normal surface velocity, pressure, and intensity. During the experiment the spectral density functions are determined using standard ensemble averaging. In the case of MatLab the spectral density function along with ensemble averaging is provided by the function **csd** in the signal-processing package. Since MatLab uses the engineering time convention, we use the complex conjugate of H due to the time dependence chosen for the NAH theory. Thus the normalized pressure in this case is

$$p(x, y, z_h, \omega) \equiv (S_{rs}(x, y, z_h, \omega)/S_{rr}(\omega))^* \\ = H(x, y, z_h, \omega)^* \quad (8)$$

This normalized pressure is used in Eq. (24) to compute the angular spectrum, the starting point for all the NAH calculations. Multiple incoherent excitations are processed in a straightforward manner.^{2,6,7}

4 RECONSTRUCTION THEORY

The signal-processing procedures outlined above are used to create holograms that form the starting point

for NAH. Once the holograms are acquired, the main aim of NAH is to provide a reconstruction of the pressure, normal velocity, and intensity at the source boundary. There are three important theoretical approaches and they are summarized below: (1) characteristic eigenfunction expansion (NAH), (2) boundary element discretization of source surface (IBEM), and (3) approximate methods [Helmholtz least squares (HELSS)].

4.1 Characteristic Eigenfunction Expansion (NAH)

An overview of this approach is shown in the outline below, which can be used to compare with the outlines in the sections following.

- Orthogonal eigenfunctions are chosen from one of the known separable solutions of the Helmholtz equation and are known analytically.
- The forward propagator (transfer function between the source surface normal velocity or pressure and the measurement surface) is known analytically.
- The reconstruction algorithm is very fast.
- Measurement and reconstruction surfaces must be constant coordinate surfaces of a separable coordinate system and must be conformal to one another.

- Eigenfunction expansion of the reconstructed field is always convergent without noise.
- Full aperture measurement (measurement surface forms a hypothetical closed surface) approach is very accurate.

Figure 3 displays a block diagram of the NAH approach including the signal-processing front end as well as the important postprocessing outputs that provide the noise analyst with ammunition to investigate noise sources. This approach is discussed in *Fourier Acoustics*,⁸ although the regularization step was added later.⁹ The postprocessing steps refer to the calculation of the acoustic intensity and the far-field pressure. Of particular significance is the use of the supersonic filter to localize hot spots of acoustic radiation on the surface of the vibrator. This quantity is often the key to locating the origins of sound. Finally the total power radiated from the structure radiated into the half-space for planar radiators, and into the full space for others, provides an important tool to discover noise problems in the vibrator.

4.2 Boundary Element Discretization of Source Surface (IBEM)

The second approach to the reconstruction of the pressure and velocity fields on a vibrating structure is given by the inverse boundary element procedure

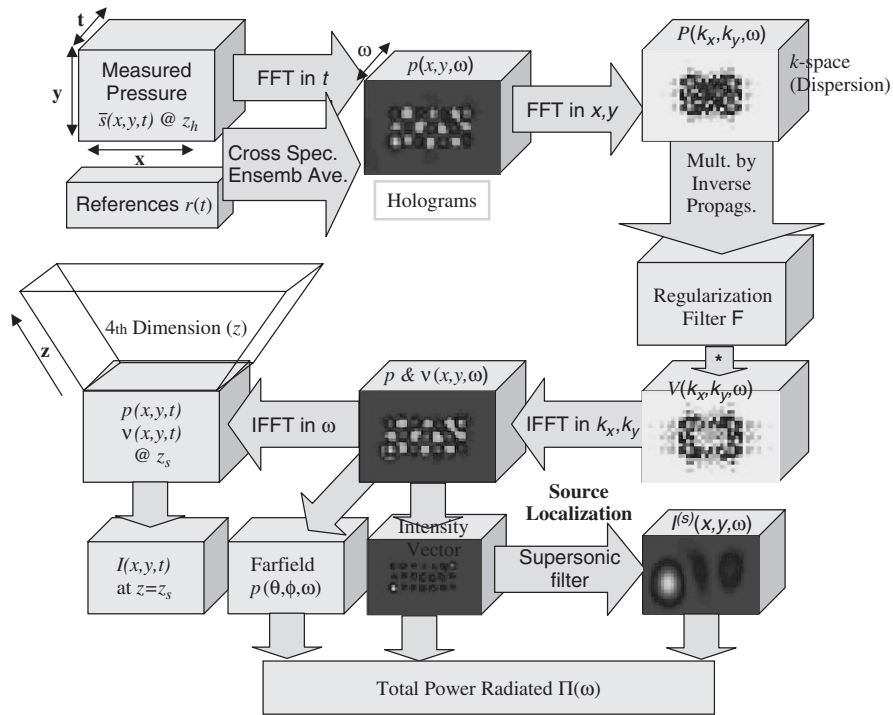

Figure 3 Flowchart of the processing steps involved in NAH starting with the measured pressure field and references at the top left. Mathematical details of these steps for planar NAH are described in the text.

(IBEM).^{8,10} An outline of this approach is provided below.

- Explicit methods are based on full Helmholtz integral equation.
- Implicit methods are based on single-layer potential, or double-layer potential, or a combination of both.
- Eigenfunctions are numerically determined.
- Forward propagator (transfer functions) is numerically determined.
- Reconstruction algorithm is slow.
- Measurement and reconstruction surfaces may have any shape.
- Full measurement aperture (measurement surface forms a hypothetical closed surface) approach is used.

This approach is illustrated in Fig. 4 and the important aspects are listed in the outline above. For comparison with Fig. 3 the added steps in the IBEM procedure are shown in a row (starting with BEM Integral Equations) just below the first row. Note that the signal-processing front end is identical in both cases. The coordinates (x, y, z) should be considered as generalized coordinates (not Cartesian) here, with the first two representing position in some sensible

fashion on the measurement surface and the third representing distance normal to the measurement surface. In this approach the pressure and velocity generally are represented by one-dimensional vectors. The transfer function between the measurement surface and the reconstruction surface is a matrix and is generated by using a BEM that discretizes the reconstruction surface using triangular or quadrilateral elements with a sufficient number of elements to represent the evanescent waves accurately (generally five to six points for the smallest evanescent wavelength of interest).¹¹

The IBEM procedures break up into two different types, direct and indirect approaches. In the direct approach the full Helmholtz integral equation, the integrand contains both single- and double-layer potentials multiplied, respectively, by the surface normal velocity and surface pressure. The approach shown in Fig. 4 is the direct approach. The indirect approach uses just a single-layer potential multiplied by a source density term. Solving for the source density is an ill-posed inverse problem, and regularization is needed. Variants of this approach use double layer and combinations of single and double layers in the integrand. We use the single-layer approach, extensively as it is much faster and more accurate than the direct method. Furthermore, recent results¹² have shown that it does not fail at the eigenfrequencies for the interior problem, as previously thought,¹³ but instead only suffers a slight

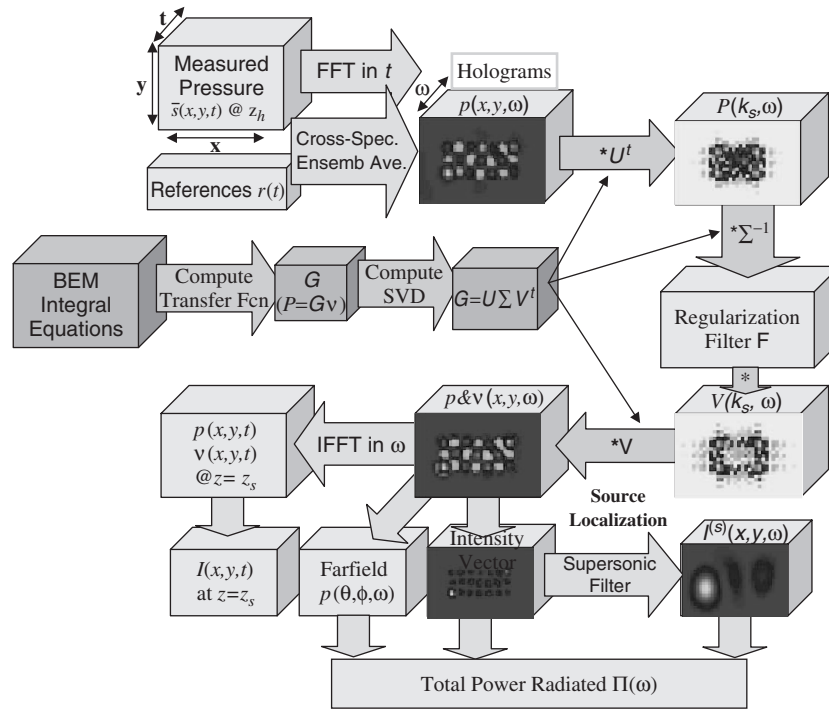

Figure 4 Flowchart of the processing steps involved in IBEM starting with the measured pressure field and references at top left. Note that most of the steps are the same as in Fig. 3.

decrease in accuracy. For the indirect method an additional step is required to recover the normal velocity or pressure on the source surface, where these quantities are written in terms of integrals over the source density (a forward, well-posed problem).

What separates NAH and IBEM from holography and a multitude of image reconstruction techniques as well as the popular time-reversal approaches is the inclusion of evanescent pressure waves in the reconstruction (formation of the image). An example of an evanescent wave is shown in Fig. 5. These evanescent pressure waves decay rapidly away from the surface of the vibrating structure of interest and cannot be retrieved from measurements made far from the surface. These waves can only be captured from measurements made close to the structure, which accounts for the use of the word *near field* in NAH. The spatial resolution of the image reconstruction in this case is independent of the actual wavelength of the sound and is determined by the subwavelength evanescent waves.

Mathematically speaking, these evanescent waves present an ill-posed inverse problem when doing reconstructions because, due to measurement noise, small perturbations in the measured pressure can lead to large perturbations in the reconstructed quantities (such as the normal surface velocity). The reconstruction is stabilized by using a regularization procedure.⁹ The velocity reconstruction is a more ill-posed problem than the pressure reconstruction and cannot be done without regularization.

Note that holograms can be made from any one of the three components of the fluid velocity instead of the acoustic pressure. Recent approaches have used normal velocity measurements to produce the hologram.¹⁴ This approach has the advantage in encountering

smaller errors in the velocity reconstruction compared with pressure measurement approaches. Direct measurement miniature velocity probes are now commercially produced.

4.3 Approximate Methods (HELs)

The third method presented in the outline above is called HELs (Helmholtz least squares)^{15–17} and is outlined below.

- Eigenfunctions (generally spherical harmonics) are chosen from one of the known separable solutions of the Helmholtz equation.
- Forward propagator is known analytically.
- Series expansion for the reconstructed field may be divergent after a certain number of terms even without noise.
- Reconstruction algorithm is very fast.

This method is based upon representing the measured data on an arbitrary surface by a series of spherical wavefunctions (made from spherical harmonics and the corresponding spherical Bessel or Hankel radial functions). Reconstructions are provided by reevaluation of the series at a different surface, and regularization is provided by a cross-validation procedure.¹⁸ Since the measurement and reconstruction surfaces are not spherical in shape, this method differs from the NAH characteristic eigenfunction expansion approach discussed above. This method is referred to as an approximate method due to the fact that the series expansion of spherical wavefunctions may diverge (even without measurement noise) after a certain number of terms depending on the geometry of the surfaces¹⁹ and on the complexity of the actual surface

Figure 5 Snapshot at $t = 0$ of a plane wave with $k_x = k_{x0} \approx k/\sqrt{2}$ and $k_y = 0$. The sinusoidal variation of pressure along the two axes is shown gray scale coded, with white-gray representing positive pressure and black-gray negative pressure and the real part is plotted. The insert on the right shows the equivalent k -space (k_x, k_y) representation. The trace wave along in the horizontal plane at $z = 0.1$ axis is supersonic and lies within the radiation circle of radius k . Since $k_y = 0$, there is no variation in the y direction (infinite wavelength).

velocity. The reconstruction accuracy also depends upon the location of the origin for the wavefunction expansion, and only an ad hoc procedure exists at the present time for location of this origin. Optimization of the origin location is a problem yet to be solved. HELS has the same advantage of speed as the NAH approach, but, unlike NAH and like IBEM, it has the advantage that it does not require measurement and reconstruction surfaces to fall on a level coordinate of a separable coordinate system.

4.4 Full and Patch Measurement Apertures

The theory for the NAH and IBEM approaches assume that the measurement and the reconstruction surfaces are complete closed surfaces. Although it is obvious from the statement of the integral equation that the source surface must be closed, it is not obvious that the measurement surface must also itself be closed. Some research has addressed the case of an open measurement surface²⁰ with a closed source surface. It is clear from this work, as well as being intuitive, that the evanescent waves cannot be recovered on the source surface outside the region represented by the normal projection of the measurement aperture down onto the source surface. In this case it would be better to eliminate the outside region completely from the problem, which reduces the size of the transfer matrices and reduces computation time significantly. This latter approach is called the partial aperture measurement approach and is shown in the second part of the outline below, which compares the full and the partial measurement aperture approaches.

- Full aperture measurement approaches:
 - Require overscanning for planar and cylindrical surfaces, closed measurement, and reconstruction surfaces for other coordinate systems such as spherical and spheroidal.
 - Time-consuming measurements and large data sets.
 - Smallest reconstruction errors.
 - Complete spatial reconstruction of the sound field is provided.
- Partial aperture measurement approaches:
 - Measurements done in a patch region, reconstruction obtained generally in a conformal reconstruction region directly below the patch.
 - Fast measurements and small data sets.
 - Larger reconstruction errors.
 - Only the acoustical quantities directly below the patch are obtained.

Patch-to-patch reconstruction is an area of current research. NAH deals with this problem by an intelligent guessing procedure to extend the measurement aperture with synthetic data (zero extension is not acceptable).^{21,22} A promising approach, called SONAH (statistically optimal near-Field acoustical

holography), avoids the aperture extension problem.²³ Research is currently underway for the IBEM problem, although results have yet to be published. By virtue of its formulation HELS is a patch-to-patch procedure and thus has the practical advantages of patch holography built in.

We would like to emphasize the continued importance of the simplest NAH system—the planar array and planar NAH. In my experience many sources of interest can be measured with a planar system, thus reducing the complexity of the analysis to a minimum. Thus the rest of this chapter is dedicated to providing a “cookbook” recipe for planar NAH, including the newest advances. We hope this will provide the experimentalist and the entrepreneur with the tools to develop a self-contained measurement system. Furthermore, advancements in microphone array technologies with the reduction in costs underscore NAH and IBEM as timely technologies. The payoffs for the experimentalist and the entrepreneur can be huge.

5 COOKBOOK RECIPE FOR PLANAR NAH

Planar NAH provides one of the most comprehensive and fastest experimental tools for diagnosing noise. Although NAH has been developed to analyze vibrators of any shape, the planar form of NAH is by far the fastest and easiest to use. Although ideal for studying vibrators with planar surfaces, the boundaries of the source need not be planar, although the reconstruction plane is limited to a tangent plane not cutting into the source.

The remainder of this chapter is dedicated to planar NAH, and the formulas presented in this chapter are aimed at computer coding using MatLab or the equivalent. A flowchart of the processing is provided in Fig. 3 discussed above. These formulas are complete, taken from the author’s book⁸ and journal publications (cited above) and his own operational MatLab code, so that the applications engineer will find it easy to develop his own or understand another’s NAH code for plane-to-plane reconstructions, for example, the STSF technique developed at Brüel & Kjaer.⁶

5.1 Fourier Transforms

The theory of NAH is based on infinite Fourier transforms (FT) in both the space and time dimensions. These are approximated in practice using the fast Fourier transform algorithm, implemented in MatLab using the function `fft`. Whereas the time-domain Fourier transforms are straightforward, the space-domain transforms are implemented using weighting factors that guarantee that the angular spectrum given in Eq. (24), which forms the basis of all the NAH calculations, is computed as accurately as possible [using Eq. (26)].

5.2 Space-Domain Infinite Fourier Transform

In Fig. 3 this step is shown by the arrow with the text “FFT in x, y ” in the top row. The infinite Fourier

transform,

$$F(k_x) = \int_{-\infty}^{\infty} f(x) e^{-ik_x x} dx \quad (9)$$

is implemented in software using a standard FFT (MatLab call **fft**), that is,

$$G_m = \text{FFT}_q[g_q] \equiv \sum_{q=0}^{M-1} g_q e^{-2\pi i q m / M} \quad (10)$$

To approximate Eq. (9) using the FFT defined in Eq. (10), given L_x is the length of the one-dimensional aperture defined by $-L_x/2 \leq x \leq L_x/2$ and M the number of points, we use

$$F(k_{xm}) \approx \Delta x w_m \text{FFT}_q \left[\underbrace{f((q - M'/2)\Delta x) w_q}_{g_q} \right] \quad (11)$$

where Table 1 gives the definition of the quantities needed for the fast Fourier transform. The weights arise from a careful discretization of the integral given in Eq. (9) and Eq. (14) (see Section 1.8.1 in

Ref. 8). For M even the weights are given by ($m = 0, 1, \dots, M$)

$$w_m \equiv (-1)^m \quad (12)$$

and for M odd

$$w_m = (-1)^m e^{-\pi i m / M} \quad (13)$$

5.3 Space-Domain Inverse Fourier Transform (IFT)

In Fig. 3 this step is shown by the arrow with the text “IFFT in k_x, k_y ” in the second row. The inverse of Eq. (9) is given by

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(k_x) e^{ik_x x} dk_x \quad (14)$$

and its implementation in software uses the inverse FFT (IFFT, MatLab call **ifft**):

$$g_q = \text{IFFT}_m[G_m] \equiv \frac{1}{M} \sum_{m=0}^{M-1} G_m e^{2\pi i q m / M} \quad (15)$$

Table 1 Definition of Important Symbols Used in This Chapter

Symbol	Description	Equation
\equiv	Definition	
\mathbf{x}	Position vector	(x, y, z)
d	Minimum distance to source	Fig. 1
$\ f(x, y)\ _2$	L2 norm	$\left(\sum_{q=1}^M \sum_{r=1}^N f(x_q, y_r) ^2 \right)^{1/2}$
k	Wavenumber	ω/c
f	Frequency (Hz)	$\omega/2\pi$
M	Number of points in x	
N	Number of points in y	
σ	Stand. dev. of noise	Eq. (27)
α	Regularization parameter	Eq. (37)
$\Pi^{(\alpha)}$	k -Space filter	Eq. (33), Eq. (34)
Δx	Microphone spacing in x	$\Delta x = L_x/M$
Δy	Microphone spacing in y	$\Delta y = L_y/N$
L_x & L_y	Size of measurement aperture	
x_q	Lattice coordinate	$x_q = (q - M'/2)\Delta x$
y_r	Lattice coordinate	$y_r = (r - N'/2)\Delta y$
Δk_x	k -Space spacing (FFT)	$\Delta k_x = 2\pi/L_x$
Δk_y	k -Space spacing (FFT)	$\Delta k_y = 2\pi/L_y$
k_{xm}	k -Space coordinates	$k_{xm} = (m - M'/2)\Delta k_x$
k_{yn}	k -Space coordinates	$k_{yn} = (n - N'/2)\Delta k_y$
q & $m = 0, 1, \dots, M-1$	Point indices	
r & $n = 0, 1, \dots, N-1$	Point indices	
M' or N' (M or N even)	Used above	$M' = M$ or $N' = N$
M' or N' (M or N odd)	Used above	$M' = M-1$ or $N' = N-1$
w_m & w_n	FFT weights in x & y	Eq. (12) & Eq. (13)
\bar{w}_m & \bar{w}_n	IFFT weights in x & y	w_m^* & w_n^*

To approximate Eq. (14) using the IFFT defined in Eq. (15) we use

$$f(x_q) \approx \frac{1}{\Delta x} \overline{w}_q \text{IFFT}_m \underbrace{[F((m - M'/2)\Delta k_x) \overline{w}_m]}_{G_m}, \quad (16)$$

where $\overline{w}_q = w_q^*$ and $\overline{w}_m = w_m^*$ (complex conjugate). Symbols are defined in Table 1.

5.4 Time-Domain Infinite Fourier Transform

In Fig. 3 this step is shown by the arrow with the text “FFT in t ” in top row. As opposed to the standard engineering convention, NAH uses the following temporal Fourier transform definition:

$$s(\omega) = \int_{-\infty}^{\infty} \overline{s}(t) e^{i\omega t} dt \quad (17)$$

The use of $e^{i\omega t}$ is the physics convention used in NAH and IBEM, whereas $e^{-j\omega t}$ is the engineering convention used in MatLab. Note that the complex conjugate $s(\omega)^*$ corresponds to the standard engineering convention (which uses $e^{-i\omega t}$ when transforming time signals). The FFT implementation of Eq. (17) is given by the complex conjugate of Eq. (10) given a time sample of T points where $g_q = \overline{s}(q\Delta t)$ and the data starts at $t = 0$ with a sample spacing Δt seconds. The frequency bin width is given by $\Delta f = 1/(T\Delta t)$ hertz.

5.5 Time-Domain Inverse Fourier Transform

In Fig. 3 this step is shown by the arrow with the text “IFFT in ω ” in the second row:

$$\overline{s}(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} s(\omega) e^{-i\omega t} d\omega \quad (18)$$

An example of the implementation using the IFFT is given in Eq. (41).

6 FUNDAMENTAL EQUATIONS IN RECTANGULAR COORDINATES

Near-field acoustical holography is based on the solutions to two fundamental equations, the Helmholtz equation and the Euler Equation.

6.1 Helmholtz Equation

$$\nabla^2 p(\mathbf{x}, \omega) + k^2 p(\mathbf{x}, \omega) = 0 \quad \text{where} \quad \nabla^2 \equiv \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad (19)$$

where a source-free, homogeneous, nonviscous fluid of density ρ_0 and constant sound speed c is assumed.

Define the *acoustic wavenumber* $k = \omega/c$ and position vector $\mathbf{x} \equiv (x, y, z)$.

6.2 Euler's Equation

$$i\omega\rho_0 \mathbf{v}(\mathbf{x}, \omega) = \nabla p(\mathbf{x}, \omega) \quad \text{where} \quad \nabla \equiv \frac{\partial}{\partial x} \hat{i} + \frac{\partial}{\partial y} \hat{j} + \frac{\partial}{\partial z} \hat{k} \quad (20)$$

and the velocity vector $\mathbf{v}(\mathbf{x}, \omega)$ (Greek letter upsilon) is

$$\mathbf{v}(\mathbf{x}, \omega) = \dot{u}(\mathbf{x}, \omega) \hat{i} + \dot{v}(\mathbf{x}, \omega) \hat{j} + \dot{w}(\mathbf{x}, \omega) \hat{k} \quad (21)$$

\hat{i} , \hat{j} , and \hat{k} are unit vectors in the x , y , and z directions, respectively. Convention: dot over a displacement quantity to indicate velocity. Displacements: $u(\mathbf{x}, \omega)$, $v(\mathbf{x}, \omega)$, and $w(\mathbf{x}, \omega)$. Note Eq. (20) represents three scalar equations.

7 PLANE WAVE SOLUTIONS (FREQUENCY DOMAIN)

The plane wave solution of Eq. (19), assuming a time dependence of $e^{-i\omega t}$ is

$$p(\mathbf{x}, \omega) = P(k_x, k_y, \omega) e^{i(k_x x + k_y y + k_z z)} \quad (22)$$

where $P(k_x, k_y, \omega)$ is an arbitrary complex constant and

$$k^2 = k_x^2 + k_y^2 + k_z^2 \quad (23)$$

Since k is a constant, the three directional wavenumbers are not independent of one another. We choose k_z as the dependent variable and k_x and k_y as independent variables:

$$k_z^2 = k^2 - k_x^2 - k_y^2 \quad \text{where} \quad -\infty < k_x < \infty, \\ \text{and} \quad -\infty < k_y < \infty$$

7.1 k Space

In Fig. 3 this step is shown by the box labeled “ $P(k_x, k_y, \omega)$ ” on the top row. The k space is defined as the space using k_x and k_y for the horizontal and vertical axes, respectively, and where the amplitudes of the angular spectra functions $P(k_x, k_y, \omega)$ given by Eq. (24) are plotted, generally using false color plots where the magnitude of P is correlated to a color spectrum. In this space an important curve is the radiation circle defined by the equation $k_x^2 + k_y^2 = k^2$, as shown in Figs. 5 and 6. The interior of this circle defines spectral components (see Fig. 5) that radiate to the far field, and the exterior defines components that are evanescent (see Fig. 6), decaying exponentially away from the vibrator and not reaching the far field.

Figure 6 Evanescent wave ($k_y = 0$) traveling in the direction of the x axis, decaying exponentially in the vertical direction. In k -space this wave falls outside the radiation circle, as shown by the large dot on the k_x axis. All evanescent waves lie outside the radiation circle and are subsonic in the horizontal plane. The wavelength in the horizontal plane at $z = 0.1$ is smaller than the acoustic wavelength.

7.2 Examples of Solutions

7.2.1 Plane Wave Solutions ($k_x^2 + k_y^2 \leq k^2$) See the example with $k_y = 0$, $k_x < k$ in Fig. 5.

7.2.2 Evanescent Wave ($k_x^2 + k_y^2 > k^2$) See the example with $k_y = 0$, $k_x > k$ in Fig. 6.

7.3 Angular Spectrum

In Fig. 3 this step is shown by the box labeled “ $P(k_x, k_y, \omega)$ ” on the top row. The coefficient $P(k_x, k_y, \omega)$ is called the angular spectrum of the pressure distribution in the measurement plane (defined to be at $z = 0$) and is given by

$$\begin{aligned} P(k_x, k_y, \omega) &= \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \\ &\quad \times p(x, y, 0, \omega) e^{-i(k_x x + k_y y)} \quad (24) \\ &= \mathcal{F}_x \mathcal{F}_y [p(x, y, 0, \omega)] \end{aligned}$$

The angular spectrum forms the springboard for all NAH calculations, and it is critical that an accurate estimate of $P(k_x, k_y, \omega)$ be obtained. Since a measurement array will not cover the infinite limits needed to calculate the angular spectrum, we require that the array is large enough to extend beyond the physical source being measured so that a finite approximation to Eq. (24) (limits in x replaced by $-L_x/2$ and $+L_x/2$ and limits in y by $-L_y/2$ and $+L_y/2$) is not severely in error. In practice, it is required that the pressure field at the edges of the array to have diminished by 30 dB in magnitude from the maximum pressure on the array. Typically, to satisfy

this condition, the array covers an area about twice the effective area of the source. Also a four- or eight-point Tukey spatial window is used to reduce the effects of wraparound error due to the FFT. Since the edges of the array are well beyond the source, the application of the Tukey window affects a small amount of the data. Zero padding can be added to the windowed data to further improve the reconstructions when the array is more than a couple of centimetres from the source. Table 2 gives the Tukey window values $T(x_q)$ for an M -point data set in one of the coordinate directions. The Tukey window is applied to the second box labeled “ $p(x, y, \omega)$ ” in Fig. 3.

A second critical requirement for accurate estimation of the angular spectrum is the choice of the sample

Table 2 Table of Tukey Window Values

Sample Number (q)	4-Point Window ($T(x_q)$)	8-Point Window ($T(x_q)$)
1	0	0
2	0.1464	0.03806
3	0.5000	0.1464
4	0.8536	0.3087
5	1	0.5000
6	1	0.6913
7	1	0.8536
8	1	0.9619
...	1	1
N-6	1	0.9619
N-5	1	0.8536
N-4	1	0.6913
N-3	1	0.5000
N-2	0.8536	0.3087
N-1	0.5000	0.1464
N	0.1464	0.03806

spacing, Δx and Δy . To prevent spatial aliasing, one requires two samples per wavelength, where the wavelength is that of the highest wavenumber evanescent waves (see Fig. 6) that are measurable above the ambient noise level. As derived in my book [see Eq. (3.23) in Ref. 8] the required spacing is given by

$$\Delta x = \Delta y = \frac{\lambda_{x \min}}{2} = \frac{27.3}{\text{SNR}} d \quad (25)$$

where d is the minimum distance from the hologram plane to the source structure (see Fig. 1), and SNR is given by Eq. (28). The array spacing is generally the same in both directions.

7.3.1 Implementation with the FFT In Fig. 3 this step is shown by the box labeled “ $P(k_x, k_y, \omega)$ ” on the top row. Equation (24) is implemented using the four- or eight-point Tukey window above with spacing dictated by Eq. (25):

$$P(k_{xm}, k_{yn}, \omega) \approx \Delta x \Delta y w_m w_n \text{FFT}_p \times [w_p T(y_p) \text{FFT}_q [w_q T(x_q) p(x_q, y_p, 0, \omega)]] \quad (26)$$

where the two FFTs are implemented in MatLab using the function **fft2**.

7.4 Estimate of Hologram Noise

Under the assumption that the noise in the pressure measurement is spatially incoherent and random (Gaussian), the standard deviation σ of the noise at frequency ω is estimated by

$$\sigma \approx \sqrt{\frac{1}{Q} \sum_{m,n} |P(k_{xm}, k_{yn}, \omega)|^2} \quad (27)$$

where the values of m and n for (k_{xm}, k_{yn}) are chosen to satisfy $\sqrt{k_{xm}^2 + k_{yn}^2} > \max(|k_{xm}|, |k_{yn}|)$, and Q is the number of points that satisfy this inequality. For Eq. (27) to be valid we must have that

$$e^{-d\sqrt{\max(|k_{mx}|, |k_{ny}|)^2 - k^2}} < \sigma/p_{\text{rms}}$$

where $p_{\text{rms}} = p(x_q, y_p, 0, \omega)_2 / \sqrt{MN}$ is the root-mean-square (rms) measured pressure in the hologram, and d is the minimum distance between the hologram and the source boundary. The *signal-to-noise ratio* (SNR) in decibels is defined by

$$\text{SNR} = 20 \log_{10}(p_{\text{rms}}/\sigma) \quad (28)$$

8 GENERAL SOLUTION TO HELMHOLTZ EQUATION

The most general solution of Eq. (19) is a sum of an infinite number of plane and evanescent waves in different directions (all with possibly different complex

amplitudes $P(k_x, k_y, \omega)$ at any given frequency ω). Given $P(k_x, k_y, \omega)$ the field is completely determined in all free space above the vibrator, $-d \leq z \leq \infty$. The *reconstructed pressure* in this space is

$$p(\mathbf{x}, \omega) = \frac{1}{4\pi^2} \int_{-\infty}^{\infty} dk_x \int_{-\infty}^{\infty} dk_y \Pi^{(\omega)}(k_\rho, z) \times P(k_x, k_y, \omega) e^{i(k_x x + k_y y + k_z z)} \\ = \mathcal{F}_x^{-1} \mathcal{F}_y^{-1} [\Pi^{(\omega)}(k_\rho, z) P(k_x, k_y, \omega) e^{ik_z z}] \quad (29)$$

where k_ρ is defined in Eq. (33). The *reconstructed velocity vector* is

$$\mathbf{v}(\mathbf{x}, \omega) = \frac{1}{\rho_0 c k} \mathcal{F}_x^{-1} \mathcal{F}_y^{-1} [(k_x \hat{i} + k_y \hat{j} + k_z \hat{k}) \times \Pi^{(\omega)}(k_\rho, z) P(k_x, k_y, \omega) e^{ik_z z}] \quad (30)$$

where $\Pi^{(\omega)}(k_\rho, z)$ is a k -space filter needed to remove noise when reconstructing the field close to the vibrator, that is, $-d \leq z \leq 0$.

8.1 Implementation with the IFFT

In Fig. 3 this step is shown by the arrow with the text “IFFT in ω ” on the second row:

$$p(x_q, y_p, z, \omega) \approx \frac{\bar{w}_q \bar{w}_p}{\Delta x \Delta y} \text{IFFT}_n [\bar{w}_n \text{IFFT}_m [\bar{w}_m \Pi^{(\omega)}(k_{\rho mn}, z) \times P(k_{xm}, k_{yn}, \omega) e^{ik_{zmn} z}]] \quad (31)$$

where $k_{zmn} \equiv \sqrt{k^2 - k_{\rho mn}^2}$ and $k_{\rho mn} \equiv \sqrt{k_{xm}^2 + k_{yn}^2}$. The two inverse FFTs are implemented in MatLab using the function **ifft2**. The same implementation is used for the reconstruction of the velocity vector. The reconstruction of the normal velocity is

$$\dot{w}(x_q, y_p, z, \omega) \approx \frac{\bar{w}_q \bar{w}_p}{\rho_0 c k \Delta x \Delta y} \text{IFFT}_n [\bar{w}_n \text{IFFT}_m [\bar{w}_m \Pi^{(\omega)}(k_{\rho mn}, z) \times P(k_{xm}, k_{yn}, \omega) k_{zmn} e^{ik_{zmn} z}]] \quad (32)$$

The in-plane velocities \dot{u} and \dot{v} are obtained by replacing k_{zmn} in front of the exponent by k_{xm} and k_{yn} , respectively.

8.2 k -Space Tikhonov Filters

In Fig. 3 this step is shown by the box labeled “Regularization filter F” on the right column. These low-pass filters^{9,24} stabilize the reconstruction and have the limiting values of 0 and 1 when $k_\rho \rightarrow \infty$ and $k_\rho \rightarrow 0$, respectively. When $z > 0$, they are not

necessary since the reconstructions are stable, and we set $\Pi^{(\alpha)} = 1$. Otherwise when $-d \leq z \leq 0$ the *standard Tikhonov filter* is given by

$$\Pi^{(\alpha)}(k_\rho, z) = \frac{|\lambda(k_\rho)|^2}{|\lambda(k_\rho)|^2 + \alpha} \quad k_\rho \equiv \sqrt{k_x^2 + k_y^2} \quad (33)$$

where α is called the *regularization parameter* given by Eq. (37) or (38). An alternative filter, which appears to be a bit more accurate, is the *high-pass Tikhonov filter* and is given by

$$\Pi^{(\alpha)}(k_\rho, z) \equiv \frac{|\lambda(k_\rho)|^2}{(|\lambda(k_\rho)|^2 + \alpha(\alpha/(\alpha + |\lambda(k_\rho)|^2))^2)} \quad (34)$$

In both these filters the *eigenvalue* $\lambda(k_\rho)$ for a pressure reconstruction Eq. (29) is

$$\lambda(k_\rho) \equiv e^{z\sqrt{k_\rho^2 - k^2}} \quad (35)$$

and for a velocity reconstruction Eq. (30) is

$$\lambda(k_\rho) \equiv \frac{\rho_0 c k}{i\sqrt{k_\rho^2 - k^2}} e^{z\sqrt{k_\rho^2 - k^2}} \quad (36)$$

Note that $z = -d$ for the reconstruction closest to the source and when $k_\rho^2 < k^2$ we use $\sqrt{k_\rho^2 - k^2} = -i\sqrt{k^2 - k_\rho^2}$.

8.3 Determination of Regularization Parameter α

1. Determination using *Morozov discrepancy principle*. In this formula we need an estimate of the standard deviation of the noise in the hologram, given by Eq. (27). To solve for $\alpha(\omega)$ we find the zero crossing of the following monotonic (in α) relationship (z held constant):

$$\|(1 - \Pi^{(\alpha)}(k_\rho, z))P(k_x, k_y, \omega)\|_2 - \sigma\sqrt{MN} = 0 \quad (37)$$

The value of α corresponding to the zero crossing is found using the MatLab function **fzero**.

2. Determination using *generalized cross validation (GCV)*. We find the minimum of $J(\alpha)$:

$$J(\alpha) = \frac{\|(1 - \Pi^{(\alpha)}(k_\rho, z))P(k_x, k_y, \omega)\|_2^2}{\|1 - \Pi^{(\alpha)}(k_\rho, z)\|_1^2} \quad (38)$$

The value of $\alpha(\omega)$ corresponding to the minimum is found using the MatLab function **fminbnd**.

8.4 Velocity Vector Angular Spectra above the Vibrator

The angular spectra at z corresponding to the velocity in the x , y , and z directions are denoted by $\dot{U}(k_x, k_y, z)$, $\dot{V}(k_x, k_y, z)$, and $\dot{W}(k_x, k_y, z)$, respectively, and are given by

$$\begin{aligned} & \dot{U}(k_x, k_y, z)\hat{i} + \dot{V}(k_x, k_y, z)\hat{j} + \dot{W}(k_x, k_y, z)\hat{k} \\ &= (k_x\hat{i} + k_y\hat{j} + k_z\hat{k}) \frac{P(k_x, k_y, \omega)}{\rho_0 c k} e^{ik_z z} \end{aligned} \quad (39)$$

They are computed by using Eq. (26). The angular spectrum of the normal velocity (and similarly for \dot{U} and \dot{V}) is defined by

$$\dot{W}(k_x, k_y, z) \equiv \mathcal{F}_x \mathcal{F}_y [\dot{w}(x, y, z, \omega)] \quad (40)$$

9 RECOVERY OF TIME-DOMAIN SIGNALS

All computations are done in the frequency domain (ω). After all the frequency bins are processed, then the time-domain signals are reconstructed using Eq. (18) implemented using the IFFT given in Eq. (15). Since only positive frequencies are computed, the negative spectrum is recovered using $s(-\omega) = s(\omega)^*$. Once the negative spectrum is set, the necessary MatLab coding is

$$\overline{p}(\mathbf{x}, t) = \text{fftshift}(\text{ifft}(p(\mathbf{x}, \omega)^*)) \quad (41)$$

where the input is conjugated to account for the fact that NAH theory uses $e^{-i\omega t}$ time convention. This operation guarantees that the resulting time-domain signal is purely real. A spectral window (Hanning or Kaiser-Bessel) is used on $p(\mathbf{x}, \omega)$ before inverse transforming to the time domain to reduce artificial ringing in the time domain-signal, which arises from the sharp cutoffs of a rectangular window.

10 FAR-FIELD PROJECTION

In Fig. 3 this step is shown by the box labeled “Farfield $p(\theta, \phi, \omega)$ ” on the bottom row:

$$p(r, \theta, \phi, \omega) = -i\rho_0 c k \frac{e^{ikr}}{2\pi r} \dot{W}(k_x, k_y, 0, \omega) \quad (42)$$

where $k_x = k \sin \theta \cos \phi$ and $k_y = k \sin \theta \sin \phi$ and (r, θ, ϕ) are standard spherical coordinates (ϕ and θ measured from the x and z axes, respectively, and $r = \sqrt{x^2 + y^2 + z^2}$). $\dot{W}(k_x, k_y, 0, \omega)$ is determined from Eq. (39) with $z = 0$. Generally, $P(k_x, k_y, \omega)$ is interpolated first in k_x and k_y by adding a wide band of zeros around $p(x, y, 0, \omega)$ and using Eq. (26). This is important at low frequencies where only a few k -space points fall within the radiation circle.

10.1 Directivity Function

Defined by

$$p(r, \theta, \phi, \omega) = \frac{e^{ikr}}{r} D(\theta, \phi, \omega) \quad (43)$$

the directivity function is

$$D(\theta, \phi, \omega) = \frac{-i\rho_0 c k}{2\pi} \dot{W}(k_x, k_y, 0, \omega) \quad (44)$$

The directivity function has the units of pascal-metres/(reference units).

11 ACTIVE AND REACTIVE INTENSITY

In Fig. 3 this step is shown by the box labeled “Intensity” on the bottom row. In Eq. (45) p and \mathbf{v} are calculated using Eqs. (29) and (30) for selected values of $z \geq -d$, and the resulting vector intensity field is plotted using the MatLab function `coneplot`.

$$\mathbf{I}(\mathbf{x}, \omega) = \frac{1}{2}(p(\mathbf{x}, \omega)\mathbf{v}(\mathbf{x}, \omega)^*) \quad (45)$$

where $\text{Re}(\mathbf{I})$ is the active intensity and $\text{Im}(\mathbf{I})$ the reactive intensity.

12 SUPERSONIC INTENSITY

In Fig. 3 this step is shown by the arrow with the text “Supersonic filter” on the bottom row. Often the active intensity on a surface has both ingoing and outgoing components, which obscure what areas of the surface actually radiate to the far field. In this case a new quantity was invented^{25,26} that removes the ingoing components, providing an unambiguous map of the radiating regions of the source. Although the spatial resolution is reduced at the lower frequencies, this approach has proven to be very powerful in source identification problems. The supersonic intensity $I_z^{(s)}$ is defined as

$$I_z^{(s)}(\mathbf{x}, \omega) \equiv \frac{1}{2}\text{Re}(p^{(s)}(\mathbf{x}, \omega)\dot{w}^{(s)}(\mathbf{x}, \omega)^*) \quad (46)$$

where $p^{(s)}$ and $\dot{w}^{(s)}$ are computed from Eqs. (31) and (32), respectively, with the a priori choice, $k_p = k$, in the k -space filter $\Pi^{(w)}(k_p, z)$ (no regularization is required) that appears in these equations. Thus the cutoff of the filter is the acoustical circle (the circle of radius k shown in Figs. 5 and 6).

13 RADIATED POWER

In Fig. 3 this step is shown by the box labeled “Total Power Radiated” at the bottom. The total power radiated into the half-space $z \geq -d$ is given by

$$\begin{aligned} \Pi(\omega) \approx & \frac{1}{2} \sum_{q=1}^M \sum_{r=1}^N \text{Re}[p(x_q, y_r, 0, \omega)\dot{w}^* \\ & \times (x_q, y_r, 0, \omega)] \Delta x \Delta y \end{aligned} \quad (47)$$

The radiated power, computed here at $z = 0$, is independent of z , however.

Acknowledgments This work was supported by the U.S. Office of Naval Research.

CHAPTER 51

CALIBRATION OF MEASUREMENT MICROPHONES

Erling Frederiksen

Brüel & Kjær
and

Danish Primary Laboratory of Acoustics (DPLA)
Naerum, Denmark

1 INTRODUCTION

Calibration has been defined by international organizations as a “set of operations that establish, under specified conditions, the relationship between values of quantities indicated by a measuring instrument or system and the corresponding values realised by standards.”¹ In the field of acoustics this means: (1) determination of the difference between the level indicated by a sound level meter and the level of the sound applied to its microphone or (2) determination of the ratio between the output voltage of a microphone and the pressure of its exciting sound wave. The latter example, the sensitivity of a microphone, is a complex quantity. Depending on the application of the microphone, both magnitude and phase may have to be calibrated. To ensure that acoustical measurement and calibration results become correct and comparable with results obtained by others, the calibration of systems, microphones, and sound calibrators should be traceable to international standards.

2 TRACEABILITY

All calibrations of sound level meters, calibrators, and microphones should be linked to an unbroken chain of comparison calibrations, which via local and national standards goes back to international standards (see Fig. 1). All methods applied in the chain should be analyzed and evaluated in detail and their uncertainty should be specified. The resulting uncertainty, which depends on the composition of the chain, should be calculated and stated with the calibration result. In this way traceability ensures a known (but not necessarily a specifically low) uncertainty, which is important for evaluation and documentation of all measurement and calibration results.

3 CALIBRATION-RELATED MICROPHONE SUBJECTS

3.1 Limitation of This Calibration Description

The sound field parameter of most common interest is the sound pressure, but the parameters sound intensity, sound power, and acoustic impedance are also frequently measured. Such measurements imply determination of both sound pressure and air-particle velocity. In principle, velocity can be directly measured with velocity-sensing microphones,² but it is most often determined indirectly with a set of pressure-sensing microphones, which simultaneously measure

the sound pressure. As instruments using such microphones are most frequently applied, are covered by international standards, and can be most accurately calibrated, only the calibration of pressure-sensing microphones is described in the following. Essentially all measurement microphones have a cylindrical body and a metallic diaphragm, which is visible when its protection grid is dismantled. The simple shape of the body and the position of the diaphragm, at the end of the body, make these microphones well-suited for both calibration and for calculation of their acoustical properties. Traditional condenser microphones have these properties plus high and well-defined acoustical diaphragm impedance, which together have made these microphones the dominating type of measurement microphone.

3.2 Microphone Standards

The International Electrotechnical Commission (IEC) has worked out and issued a series of measurement microphone and calibration standards under the common title and number Measurement Microphones—IEC 61094. Part 1 and Part 4 of the series specify required properties of laboratory standard microphones³ and working standard microphones,⁴ respectively. Laboratory standard microphones are mainly calibrated and kept as national standards but are also used as reference standards with comparison calibration systems, while working standard microphones are the microphones used for essentially all other kinds of acoustical measurements.

3.3 Microphones and Sound Fields

The sensitivity and frequency response of a microphone depends on the type of sound field. The sensitivity is, therefore, generally specified for one of the following types of sound field: (a) a free field⁵ with a plane wave, (b) a diffuse field,^{6,7} and (c) a pressure field, that is, a field, where magnitude and phase of the pressure are independent of the position. At low frequencies, where the microphone diameter is small compared with the wavelength of the sound (say $d < \lambda/30$), the sensitivity does not significantly depend on the type of field. The sensitivity of microphones less than 24 mm is thus the same for all field types up to about 500 Hz. As the frequency 250 Hz is well below this limit, it has become a commonly used sound calibrator and system calibration frequency that can be applied with all types of sound field. The

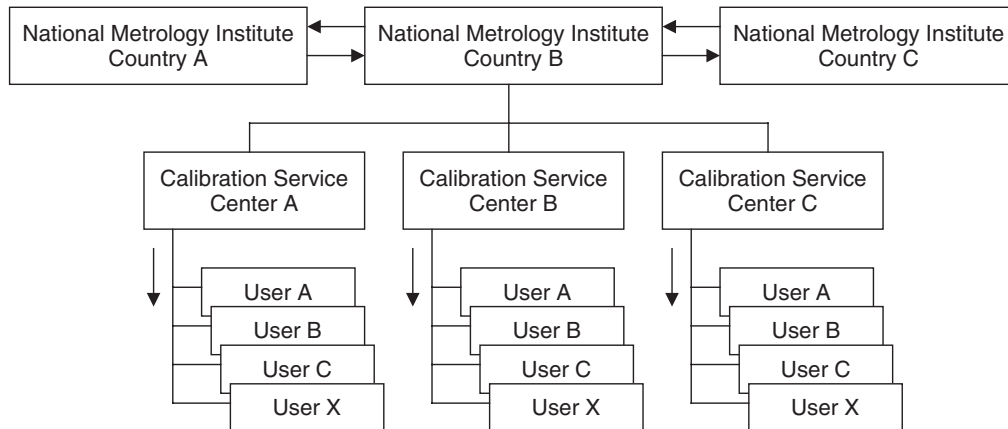

Figure 1 Typical calibration hierarchy with service centers that ensure traceability to national and international standards.

field dependency increases with the diameter to wavelength ratio and thus with frequency. It is typically of the order 0.05 to 0.2 dB at 1000 Hz but may become as high as 10 to 15 dB at the highest operation frequencies (see Fig. 2). Therefore, specific models of microphone have been optimized, with respect to frequency response, for use in the different types of sound field. Prior to any acoustical measurement, both types of microphone and calibration should thus be selected in accordance with the type of sound field that occurs at the measurement site.

3.4 Open-Circuit and Loaded-Microphone Sensitivity

Typically, the capacitance of laboratory standard and measurement microphones is between 12 and 60 pF, but it can be as low as 3 pF for the smallest types of microphone. Due to the low capacitance, cables cannot be connected directly to the microphones without violating their function. A preamplifier with high-input and low-output impedance must, therefore, be connected to the output terminal of the microphone. Even such a preamplifier loads the microphone by its input capacitance and causes a sensitivity reduction that generally needs to be taken into

account. By most calibrations the nonloaded (open-circuit) sensitivity is determined and reported for the microphone. The loaded sensitivity might be measured, for specific microphone–preamplifier combinations, or it may be obtained by adding a predetermined nominal correction, valid for the types of microphone and preamplifier, to the open-circuit sensitivity.

The response of a microphone may be stated as sensitivity (M) in volts per pascal (V/Pa) or in terms of sensitivity level (L_M) in decibels related to the reference sensitivity (M_{ref}), that is, 1 V/Pa;

$$L_M = 20 \log \frac{M}{M_{\text{ref}}}$$

3.5 Microphone Preamplifiers

Modern preamplifiers have very high input impedance. The input resistance may be as high as 10^{10} to $10^{11} \Omega$ with a parallel capacitance as low as 0.1 to 0.2 F. The voltage gain of the amplifier built into the preamplifier unit is in most cases near to unity (1 or 0 dB). The electrical response of the microphone and preamplifier is essentially flat over the range from say 20 Hz to 100 kHz (Fig. 3). Therefore, its influence on the microphone frequency response is normally neglected in secondary microphone calibration. In connection with primary calibration and very precise measurements, the electrical response has to be measured.

3.6 Insert Voltage Technique

The insert voltage technique⁸ is applied when measuring the electrical gain and frequency response of a microphone and its preamplifier with a possible influence of a loading cable (see Fig. 4). The principle is to measure the gain of the circuit with a voltage that is inserted directly into series with the microphone. During the measurement this voltage replaces the sound generated (open-circuit) signal (u_{oc}) of the microphone. The gain ($u_{\text{out}}/u_{\text{ins}}$) of the circuit, which

Figure 2 Free-field, diffuse-field, and pressure-field frequency responses of a free-field microphone (12.7 mm) deviate from each other at higher frequencies.

Figure 3 Electrical frequency responses of a typical measurement microphone ($C = 18$ pF) and preamplifier ($C_{in} = 0.2$ pF, $R_{in} = 10$ G Ω , $R_{out} = 30$ Ω) loaded with cable ($C = 3000$ pF).

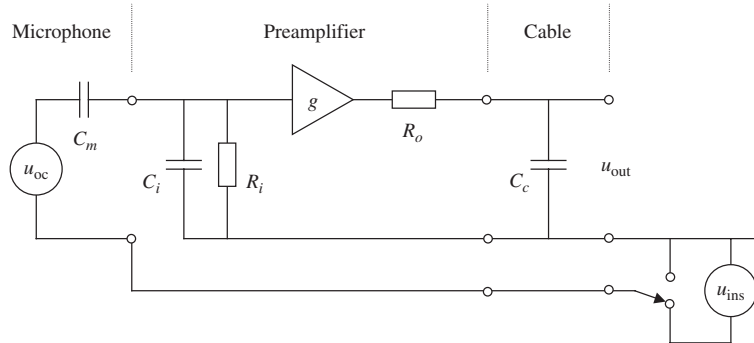

Figure 4 Principle of insert voltage technique for measurement of electrical gain.

consists of microphone capacitance (C_m), preamplifier input impedance ($C_i \neq R_i$), amplifier gain (g) and output resistance (R_o), is measured with the loading of the cable capacitance (C_c). Often the gain (G_{mp}) is measured only at the preferred microphone calibration frequency and the reference frequency for the frequency response definition (often 250 Hz). This gain is used with the open-circuit sensitivity of a microphone to calculate its sensitivity in combination with a preamplifier. The gain in the midfrequency range is determined by

$$G_{mp}[\text{dB}] \cong 20 \log \frac{C_m}{C_m + C_i} + g[\text{dB}]$$

where G_{mp} = electrical gain of microphone and preamplifier at reference frequency (250 Hz)

C_m = capacitance of microphone

C_i = input capacitance of microphone preamplifier

g = gain of voltage amplifier built into the preamplifier unit

The nominal gain valid for a specific combination of types of microphone and preamplifier is commonly used together with an individually measured microphone sensitivity to determine the sensitivity of a specific microphone and preamplifier combination:

$$M_{mp}[\text{dB re.1 V}] = M_{oc}[\text{dB re.1 V}] + G_{mp}[\text{dB}]$$

where M_{mp} = combined sensitivity of microphone and preamplifier

M_{oc} = open-circuit sensitivity of microphone

G_{mp} = electrical gain of microphone and preamplifier

The insert voltage technique is thus a method used in connection with other acoustical calibration techniques and is not a stand-alone method.

4 CALIBRATION METHODS

4.1 Sound Fields of Application and Calibration

4.1.1 Selection of Calibration Method The type of microphone and its calibration should be selected in accordance with the type of sound field at the measurement site. This means that the frequency response calibration should be valid for the relevant type of field but not necessarily be performed with that type of field. For any specific type of microphone there are essentially fixed ratios between the responses related to the three principal types of sound field. Therefore, if these ratios have once been determined and made generally available, all responses can be worked out after calibration of one of them. This fact is very important for calibration of common microphone types, as especially free-field and diffuse-field calibrations are technically difficult and costly to perform. Usually free-field and diffuse-field responses are thus determined by applying corrections, either to the pressure-field response or, most commonly, to the so-called electrostatic actuator response (see below), which is quite easily measured.

4.2 On-Site Calibration Methods

4.2.1 Single-Frequency Calibration of Measurement System On-site calibration of measurement systems is common and highly recommended. A system can be calibrated by analog gain adjustment or by data insertion according to the sensitivity stated on the microphone calibration chart or certificate. However, a system can also be calibrated by correcting its gain or settings until it displays the stated level of a connected sound calibrator. Any one of the two methods is fine with instruments that are frequently used and known to perform properly. However, it is recommended, especially in connection with critical and costly experiments, to apply both methods successively. This will reveal possible instrument defects or wrong settings and prevent that errors get "hidden" by a compensating but nonproper gain setting. Together the methods will, effectively, increase the confidence of correct system performance. Typically, the deviation between the two methods should not exceed a few tenths of a decibel. If the goal is met, one can subsequently either make no further correction or adjust the reading to match the level of the calibrator. The choice between the methods should depend on their uncertainties, which are generally of same order of magnitude.

Figure 5 Principle of sound calibrator with integrated monitor microphone in pressure-controlling feedback loop.

Specifications of sound calibrators are given in national and international standards.⁹ Most common types of sound calibrator are intended for calibration of measurement systems at one frequency only. Their operation frequency may be 250 Hz, but might also be 1000 Hz and comply with the requirements of national and international standards for sound level meters.¹⁰ Older types of calibrator generally contained just an electrical generator and a sound source, while newer types have a built-in microphone that measures and controls the pressure generated in the coupler cavity via a feedback loop (see Fig. 5). The newer design leads to calibrators that are more stable and less dependent on ambient conditions because the sound pressure does not depend on a, generally, less stable sound source but rather on a more stable microphone. Furthermore, due to the feedback loop, such calibrators get lower acoustical output impedance and can be designed to become essentially independent of the load impedance made up by the inserted microphone.

These calibrators, which basically work with small coupler cavities, produce a pressure field. This means that no correction should be applied if the microphone to be calibrated is to be used in a pressure field, say, in a coupler used in the testing of hearing aids. However, if the microphone is part of a free-field sound level meter, one should be aware that its free-field sensitivity for 0° incidence is typically 0.1 to 0.3 dB higher (see microphone or instrument manual) than its pressure-field sensitivity at 1000 Hz. Therefore, to make the instrument read correctly under free-field conditions, the reading with the calibrator should be correspondingly lower than the stated calibrator level. As the diffuse- and pressure-field sensitivities of both one- and half-inch microphones are essentially equal at 1000 Hz, no such correction should be made, when calibrating systems for diffuse-field measurements.

4.2.2 System Frequency Response Verification by Multifrequency Calibrator

A multifrequency calibrator works at one frequency only, but the frequency can be changed in steps, usually by one octave over a range from say 31.6 Hz to 16 kHz. Generally, such calibrators apply the feedback principle (see above), which can work with coupler cavities so small that they can be operated at the highest mentioned frequency. This type of calibrator is widely used for sensitivity calibration at either 250 or 1000 Hz and for additional frequency response verification over its full range. At frequencies higher than 1000 Hz the pressure on the diaphragm of the inserted microphone differs from that of the calibrator cavity because of the influence of the diaphragm protection grid. Therefore, high-frequency verification of frequency response is only possible if corrections have been measured and are specified for the particular type of microphone. Without corrections this type of calibrator is used for checking stability of frequency response over time.

4.2.3 Application of Pistonphones Some types of sound calibrator, called pistonphones, are based on a mechanical operation principle. Pistonphones for use in the field are usually equipped with two pistons driven by a rotating cam disk in and out of the calibrator cavity, where the sound pressure is generated (see Fig. 6). The precisely controlled sinusoidal displacement of the pistons creates a well-defined sound pressure that can be calculated by

$$p \cong \gamma p_{\text{amb}} \frac{2Sd}{\sqrt{2}V}$$

where p = root-mean-square value of created sound pressure

γ = ratio of specific heats of the gas in the cavity ($\gamma = 1.402$ for dry air at 20°C)

Figure 6 Principle of hand-held pistonphone. The cam disk in the center displaces the pistons into the surrounding cylindrical calibrator cavity.

p_{amb} = ambient static pressure

S = mean cross-sectional area of the pistons

d = peak displacement of the pistons

V = volume of coupler cavity (including volume of loading microphone)

The equation is fully valid for adiabatic compression conditions, but, in practice, a heat conduction effect that occurs at the wall of the cavity, especially at low frequencies, reduces the pressure slightly.⁸ Typically, such pistonphones work at 250 Hz. As their sound pressure is proportional to the ambient pressure, a precision barometer must follow any pistonphone for accurate determination of its sound pressure. Pistonphones are generally very stable over time. Therefore, they are used as precision field calibrators and as reference standards for comparison calibration of other types of sound calibrator.

4.2.4 Sound Intensity and Particle Velocity Calibration

The uncertainty of sound intensity and particle velocity measurements is highly influenced by even small-phase deviations between the applied measurement channels. As microphones, preamplifiers, and amplifiers of the analyzer all contribute to the resulting phase difference, it is important to verify that a user-combined system meets his requirements. Any difference between the phase responses leads to a false intensity that may either add to or subtract from the measured intensity of the field. Therefore, IEC 61043¹¹ prescribes minimum requirements to pressure-residual intensity index, which is the difference between the pressure level and the residual (false) intensity level that are measured, when the microphones of the probe are exposed to the same pressure. Calibrators that cover the range from 20 Hz to 10 kHz have been designed and are commercially available for this purpose. Particle velocity measurements are also highly influenced by a possible gain difference. This type of error may be detected and reduced with the calibrator by making a minor gain adjustment in one of the channels.

Such calibrators are also designed for absolute pressure level calibration of probes and some even for calibration of intensity level. Intensity is simulated by two signals of controlled pressure and controlled phase difference. An intensity level uncertainty of about 0.12 to 0.16 dB is obtainable at 250 Hz.

4.3 Methods of Calibration Service Centers

4.3.1 Secondary Calibration A secondary calibration is the calibration of a secondary standard, whose value is assigned by comparison with a primary standard of the same quantity.¹ Such calibrations may be performed by national metrology institutes but are most often made by calibration service centers.

4.3.2 Sensitivity Comparison Calibration Sensitivity determination by comparing the output of an unknown microphone with that of a known reference standard is the most commonly used method. This type of calibration is generally made at one frequency only,

Figure 7 Principle of comparison coupler with built-in source. Operation is possible up to 20 kHz due to its symmetry and the closely mounted diaphragms.

while calibration at other frequencies is performed as a measurement of the frequency response, which is normalized at the sensitivity calibration frequency (typically 250 Hz). The comparison calibration can either be performed by substitution or by simultaneous excitation of the unknown and known microphones. The latter method has the advantage that no uncertainty is related to the microphone loading of the sound source. However, in addition to a two-channel measurement system, the method requires an active two-port coupler (see Fig. 7) or a corresponding microphone mounting. IEC 61094-5¹² describes comparison calibration of microphones with active two-port couplers and mounting jigs.

The equation for the sensitivity calculation is shown below. As the sensitivity of a microphone depends on ambient conditions, it is common to state the calibration result at standard reference conditions [101.325 kPa, 23°C, 50% RH, (relative humidity)]. Therefore, corrections that account for the sensitivity difference between measurement and reference conditions are inserted in the equation. These corrections can only be performed, if sensitivity coefficients for static pressure, temperature, and relative humidity are available for both microphones:

$$\begin{aligned}
 M_X [\text{dB re. 1 V/Pa}] &= M_R [\text{dB re. 1 V/Pa}] \\
 &+ 20 \log \frac{u_X}{u_R} + 20 \log \frac{G_R}{G_X} \\
 &+ \text{Cor}_{\text{Ps}} + \text{Cor}_T + \text{Cor}_{\text{RH}}
 \end{aligned}$$

where M_X = sensitivity of microphone being calibrated

M_R = sensitivity of reference microphone

u_X = output voltage of microphone being calibrated

u_R = output voltage of reference microphone

G_X = electrical gain of channel with microphone being calibrated

G_R = electrical gain of channel with reference microphone

Cor_{Ps} = sensitivity correction for ambient pressure

Cor_T = sensitivity correction for ambient temperature

Cor_{RH} = sensitivity correction for ambient humidity

4.3.3 Frequency Response Calibration by Electrostatic Actuator

In calibration service centers and by manufacturers, where many measurement microphones are calibrated, the most commonly applied method for frequency response calibration is the electrostatic actuator method. This method is fast and it only requires “normal” laboratory conditions (no specific acoustical measurement rooms). An electrostatic actuator excites the diaphragm of the microphones by electrostatic forces. The sound, which under certain conditions can be heard during actuator calibration, is thus not generated by the actuator but by the excited microphone diaphragm. This diaphragm-generated sound is the reason that the measured actuator response differs from the pressure response of the microphone. The difference (in decibels), which is essentially zero at lower frequencies, is about +0.1 dB at 1 kHz and −1.5 dB at 10 kHz for highly sensitive microphones (1-inch pressure microphones with 50 mV/Pa) that have diaphragms with low acoustic impedance. For less sensitive microphones the difference is significantly smaller. However, the difference is essentially the same for all units of a given type or model of microphone. Therefore, corrections can be applied with actuator calibration results to determine free-field, diffuse-field, and also pressure-field responses. The actuator method is generally used between 20 Hz and 200 kHz. It may also be used at higher and lower frequencies, though with low-frequency calibration one should be aware that the actuator excites the microphone diaphragm only. This means that the low-frequency roll-off of the free- and diffuse-field responses, which is caused by the static pressure equalization vent of the microphone, cannot be measured by this method.

An actuator is a metallic plate placed in front of and in parallel with the microphone diaphragm that must consist of metal or have an electrically conducting layer on its external side. Actuators are typically driven with 30 to 100 V ac (alternating current) and 800 V dc (direct current) (see Fig. 8), and they generate an equivalent sound pressure level of 94 to 100 dB. For details, see Ref. 13 and IEC 61094-6.¹⁴

4.3.4 Frequency Response Calibration by Small-Volume Active Coupler

Small-volume comparison calibration is an alternative method for

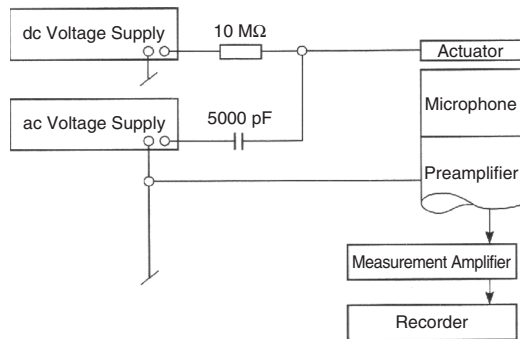

Figure 8 Block diagram of electrostatic actuator calibration system.

frequency response calibration. Its major advantage over electrostatic actuator calibration is that microphones to be calibrated do not need to have electrically conducting diaphragms and that they can be calibrated without dismantling their diaphragm protection grids. The method implies thus less risk of destroying microphones and can be used under less controlled working conditions. Like the actuator method this method requires application of corrections to obtain frequency responses that are valid in the principal types of sound field. Disadvantages are that sound field corrections have not been measured and published to the same extent as for the actuator method and that the frequency range of the method is less wide, due to resonance phenomena in the applied couplers. The uncertainty that can be achieved with the method is very good (say 0.05 dB, $k = 2$) at lower frequencies, but it increases significantly from about 4 up to 16 kHz, which is a typical upper limit for calibration of half-inch microphones. A sketch of a small-volume active coupler is shown in Fig. 7. IEC 61094-5¹² describes the method in greater detail.

4.3.5 Sound Field Corrections Frequency responses that are measured with electrostatic actuator or with small-volume comparison couplers are generally not directly applicable. Corrections should be applied to the measured responses to obtain responses that are valid under free-field, diffuse-field, or pressure-field conditions. The measured responses are usually normalized at 250 Hz, where the influence of the type of sound field on the microphone sensitivity is essentially zero for microphones of diameter less than say 25 mm. The necessary sound field corrections may be worked out by acoustical metrology institutes or by leading manufacturers, who master primary calibration methods and have the necessary acoustical facilities. Free-field corrections depend on angle of sound incidence on the microphone body. Free-field microphones are generally optimized for and applied with axial sound incidence on the front of their diaphragms (called 0° incidence) and should also be calibrated for this incidence. The free- and diffuse-field corrections account for the change of sound pressure in the measurement point, which is due to the presence of the microphone body and is caused by diffraction and reflection of the sound. The correction is a function of microphone dimensions and shape of body and protection grid. A free-field response, obtained by adding the correction to the measured electrostatic actuator response, is shown in Fig. 9. More details and data can be found in the Brüel & Kjær Microphone Handbook.¹⁵

4.3.6 Phase Response Comparison Calibration

Measurement of sound intensity is most often performed in accordance with an internationally standardized method¹¹ that is based on pressure measurements only. Intensity measurement probes intended for one-, two-, or three-dimensional measurements are equipped with a pair of pressure-sensing microphones for each dimension. The microphone pair measures the pressure at two points with predefined distance on the probe measurement axis (Fig. 10). The intensity is obtained

Figure 9 Corrections added to a measured electrostatic actuator response to obtain the microphone response curve valid for free-field conditions.

Figure 10 One-dimensional intensity measurement probe equipped with pressure-sensing microphones.

by multiplying pressure and air particle velocity, which are represented by functions of sum and difference of the measured pressure values, as shown in

$$\bar{I}_r = \frac{p_1(t) + p_2(t)}{2} \int \frac{p_1(t) - p_2(t)}{\Delta r_0 \rho_0} dt$$

where the bars indicate time average of intensity and $p_1(t)$, $p_2(t)$ = instantaneous sound pressure measured by microphones 1 and 2

Δr_0 = distance between pressure measurement points

ρ_0 = density of gas (air)

t = Time

The method is only applicable if the phase response characteristics of the applied microphones are essentially equal. Even a small deviation between the phase responses can lead to a significant error of the measured velocity and thus also of the intensity.

IEC 61043 specifies minimum acceptable pressure-residual intensity indices for probes and measurement systems. The indices are differences between the levels of pressure and residual intensity that are measured by the system and related to probe and system, respectively, when the same signal is applied to the two microphones. The standard specifies indices for a fixed microphone distance (25 mm), which for the microphones can be converted to deviations between their phase responses (see Fig. 11). The conversion is made with the following equation below:

$$\Delta\phi \cong \frac{\Delta R f}{c} 360 \times 10^{-\text{Index}/10}$$

where $\Delta\phi$ = maximum phase response deviation

ΔR = nominal microphone distance (25 mm)

f = frequency

Index = minimum index specified by IEC61043

The uniformity requirements to phase responses are not met by randomly selected pairs of measurement microphones. Different microphone mechanisms cause phase deviations that are generally far too large, both at low and at high frequencies. Therefore, microphones are selected to form suitable matching pairs.

The pressure on the diaphragm and that at the static pressure equalization vent determine the low-frequency phase response of a microphone and thus also the phase response deviation between two microphones. Therefore, microphone pairs that are to be compared with respect to phase response deviation must be exposed to essentially the same pressure at both diaphragms and vents during the calibration.

Figure 11 Upper limits (IEC 61043) of phase response deviation for pairs of intensity measurement microphone and related limit of phase calibration uncertainty.

Figure 12 Phase response comparison coupler for selection and calibration of matched pairs of microphone.

To ensure sufficient pressure uniformity over a wide frequency range, the coupler (see Fig. 12) used with the measurement must be as small as possible and situate the microphones placed close to each other with their diaphragms “face to face.” This positioning gives pressure uniformity also at high frequencies, where only the pressure at the diaphragms is significant. This type of coupler can work from a few hertz up to about 6 kHz and 10 kHz with half-inch and quarter-inch microphones, respectively.¹⁶ Couplers designed with two sound inlets can work at frequencies that are about 50% higher. The estimated calibration uncertainty ($k = 2$) is less than 12% of the requirements in the standard.

4.3.7 Low-Frequency Calibration The low-frequency response of a microphone depends on the time constant of its static pressure equalization system and also on, whether the venting channel is exposed to the sound field or not. Typically, the response of a microphone rolls off by 3 dB at a frequency between 1 and 3 Hz, if the vent is exposed, while the response is essentially flat to dc if it is nonexposed. At frequencies lower than 10 times the -3 dB frequency, it is important to choose a low-frequency calibration method that will expose the microphone diaphragm and vent to the sound in a way that corresponds to that existing on the intended measurement site.¹⁵ Specially designed pistonphones and couplers with wall-mounted reference microphones are commonly used for low-frequency calibration.

4.4 Methods of Microphone Testing

4.4.1 Environmental Testing The sensitivity of any measurement microphone is to some degree influenced by the ambient conditions.^{15,17} The international standards for laboratory³ and working standard microphones⁴ require that the magnitudes of pressure, temperature, and relative humidity coefficients do not exceed certain limits. These coefficients are most often measured with electrostatic actuators, whose excitation of the microphone is essentially independent of the ambient parameters. It should be noted that the actuator measurement determines changes of microphone pressure sensitivity only—it does not measure changes of diffraction and reflection. Changes of free- and diffuse-field corrections are small and are generally ignored but may be estimated from changes

of speed of sound and their influence on the wavelength. This is influenced by temperature and, to a small degree, by the ambient pressure and humidity.

4.4.2 Dynamic Range Testing The dynamic range of condenser microphones is generally large compared with the range of commonly occurring and measured sound pressure levels. Sometimes measurements must be made near to the lower limit—the level of the inherent noise of the microphone—or near to the upper limit, which is usually determined by microphone distortion or by its preamplifier clipping of the signal.¹⁵

Inherent noise of a microphone can be measured by placing the microphone in a sound-isolating chamber.¹⁸ This is typically a sealed metal cylinder with walls of 10- to 20-mm thickness and a volume of 1000 to 2000 cm³. Such a chamber can be used for broadband noise measurements down to less than 0 dB (threshold of hearing), if it is isolated from vibration.

High-level calibration or test devices have been designed with horn-drivers, shakers, pistonphones, and resonating tubes, which all work at relatively low frequencies.¹⁹ Linearity is measured with such systems by comparing the device under test with selected high-level reference microphones. One example is a resonating tube system that at 500 Hz can measure level linearity and distortion from an SPL of 94 dB to 174 dB (0.1 bar) with uncertainty less than 0.025 dB and 0.5%, respectively, at the highest level.^{20,21}

4.5 Methods of National Metrology Institutes

4.5.1 Primary Calibration The sensitivity of measurement microphones is most often determined by comparison with that of a reference microphone, which is usually a laboratory standard microphone. Also this reference might have been calibrated by comparison; however, this is not possible for the upper microphone in the calibration hierarchy. It will have to be calibrated by a “primary calibration” method that determines microphone sensitivity based on nonacoustical, that is, physical, mechanical, and electrical, parameters.

Microphone reciprocity calibration is an example of a primary method. It was invented in the 1940s, and since then the method has become refined and standardized and is now the dominating primary method for both free-field²² and pressure-field calibration.⁸

Table 1 Uncertainty of Pressure Reciprocity Calibration of Leading National Metrology Institute

Uncertainty ($k = 2$)		20 Hz	32 Hz	63 Hz–4 kHz	10 kHz	20 kHz	25 kHz
Pressure field	LS1	0.06 dB	0.04 dB	0.03 dB	0.08 dB	—	—
	LS2	0.08 dB	0.05 dB	0.04 dB	0.04 dB	0.08 dB	0.12 dB

The reciprocity calibration technique, which is considerably more complex and time consuming than comparison calibration techniques, is mainly applied by national metrology institutes and by leading microphone manufacturers.

4.5.2 Principle of Reciprocity Calibration The reciprocity calibration method²³ requires reciprocal transducers,²⁴ like condenser microphones, that are passive and can work both as sound sensors and sources. The calibration technique is based on the measurement of transfer functions for pairs of microphones that are operated as source and sensor, respectively. The microphones are coupled together in an acoustically well-defined way, while the overall transfer function, the ratio between sensor output voltage and source input current, is measured. From this ratio, called the electrical transfer impedance, and from the acoustical coupling or transfer impedance the microphone sensitivity product may be calculated:

$$M_1 M_2 = \left(\frac{Z_e}{Z_a} \right)_A$$

M_1, M_2 = sensitivities of microphones 1 and 2

Z_e/Z_a = ratio of electrical and acoustical transfer impedance

By having three microphones (1, 2, 3) and by making three measurements (A, B, C) with the three possible microphone combinations (1–2, 1–3, 2–3), the sensitivities of the microphones can be calculated from values of measured electrical and calculated acoustical transfer impedance:

$$\begin{aligned} M_1 M_2 &= \left(\frac{Z_e}{Z_a} \right)_A & M_1 M_3 &= \left(\frac{Z_e}{Z_a} \right)_B \\ M_2 M_3 &= \left(\frac{Z_e}{Z_a} \right)_C \end{aligned}$$

Different microphone responses can be obtained by reciprocity calibration by applying different microphone coupling principles. The pressure-field responses are thus obtained by coupling the microphones with the

air (or gas) inside a small closed cavity, while the free-field responses are obtained with open-air coupling in a space that has no disturbing sound reflecting surfaces (an anechoic room).

4.5.3 Pressure Reciprocity Calibration Several national metrology institutes around the world offer a pressure reciprocity calibration^{8,25} service for laboratory standard microphones. Typically, the frequency range is from 20 Hz to 10 kHz for 1-inch (LS1) and 20 Hz to 20 kHz for 0.5-inch (LS2) microphones, but some institutes have experience with calibration at both lower and higher frequencies. Standing waves in couplers determine the upper frequency limit of pressure reciprocity calibration. The wave problem can be reduced either by filling hydrogen, which has higher speed of sound than air, into the coupler or by shaping the couplers as “near ideal” acoustical transmission lines. This type of coupler, called a plane-wave coupler, performs in an analyzed and predictable way and is now applied for most primary pressure calibrations. Table 1 shows typical calibration uncertainty values.

4.5.4 Free-field Reciprocity Calibration^{22,26}

Only few laboratories offer a free-field reciprocity calibration service. The theory behind free-field reciprocity calibration is simpler than that of pressure reciprocity, but technically it is much more difficult to perform. The major reason is that condenser microphones are very weak sound sources, when applied in the open space. This leads to serious noise and cross-talk-related measurement problems. As this is the case especially at lower frequencies, the lower limit of free-field calibration services is generally about 1 to 3 kHz. Free-field calibration can be performed up to about 25 and 50 kHz for 1-inch and 0.5-inch microphones, respectively. Table 2 shows typical calibration uncertainty values.

4.5.5 Free-Field Corrections of Laboratory Standard Microphones

Fortunately, there is, essentially, a fixed ratio between the free-field and the pressure-field sensitivities of any microphone or model of microphone. Therefore, if this ratio is known, the free-field sensitivity can be calculated by adding a correction to the pressure-field sensitivity, which

Table 2 Uncertainty of Free-Field Reciprocity Calibration of Leading National Metrology Institute

Uncertainty ($k = 2$)		1 kHz	2 kHz	4 kHz	8 kHz	10 kHz	20 kHz	40 kHz
Free field	LS1	0.10 dB	0.08 dB	0.07 dB	0.07 dB	0.08 dB	0.15 dB	—
	LS2	0.12 dB	0.10 dB	0.08 dB	0.07 dB	0.07 dB	0.09 dB	0.15 dB

is more easily and more accurately measured. Free-field corrections for the following laboratory standard microphones: Brüel & Kjær Type 4160 and Type 4180, Tokyo Rico Type MR103 and Type MR112, and Western Electric Type 640AA have been measured and calculated and are stated in the manufacturer specifications, standards, and research reports. Newer and internationally agreed free-field correction data have been published for Laboratory Standard Microphones types LS1 and LS2 in an IEC Technical Specification TS 61094-7. These corrections²⁹ are supported by several measurement results obtained with the B&K microphones Types 4160 and 4180.

4.5.6 Determination of Diffuse-Field Frequency Response

Diffuse-field reciprocity calibration²⁷ is, in principle, possible, but it is associated with several problems that have presently not been sufficiently analyzed and described to make the method practically applicable.²⁸ Therefore, diffuse-field responses of microphones are generally calculated from free-field responses measured for different angles of sound incidence. The angles are typically spaced by 10° and cover the range from 0° to 180° . During the calculation a weighting factor is applied with the correction of each measured angle to account for its probability of occurrence in a diffuse sound field. This method of calculating the diffuse-field sensitivity from a series of free-field responses and the diffuse-field correction from a series of free-field corrections is standardized and is the commonly used method for determining diffuse-field responses. Diffuse-field corrections that are determined by this method are frequently applied with electrostatic actuator measurements by service centers for secondary microphone calibration.

4.5.7 Calibration of Reference Sound

Calibrators The International Standard for Sound Calibrators IEC60942⁹ specifies a laboratory standard calibrator named Class LS. This class of calibrator includes reference standard pistonphones that are mainly used by national metrology institutes and calibration service centers for comparison calibration of other types of calibrators. The sound pressure of pistonphones might be determined by calculation after measurement of their mechanical dimensions, speed of rotation, and ambient conditions. However, such laboratory sound standards are generally calibrated by measuring the sound pressure by one or more reference standard microphones, which are calibrated by the pressure reciprocity method. This method may lead to an uncertainty of less than 0.05 dB ($k = 2$).

CHAPTER 52

CALIBRATION OF SHOCK AND VIBRATION TRANSDUCERS

Torben Rask Licht
Brüel & Kjær
Naerum, Denmark

1 INTRODUCTION

This chapter describes various methods used today for calibration of vibration and shock transducers. The general concepts of sensitivity, traceability, and hierarchy are briefly introduced. A short description of the general measurement principles is given, stressing the difference between relative and absolute measurement principles. The important features of the most common types of transducers and preamplifiers are described, as this is important knowledge to avoid errors in the calibration process. Over time many methods have been used and might still be useful, but this chapter is limited to the most important methods. As the range of frequencies and amplitudes covered by vibration transducers is very large, it will often be necessary to apply several methods to give a complete calibration of a transducer. The chapter describes calibrators, comparison to a reference transducer, and primary calibration methods. Typical attainable uncertainties are given to help the user to select the method most appropriate for a given measurement task.

2 SENSITIVITY AND TRACEABILITY

To calibrate a transducer is to determine its sensitivity, sometimes referred to as the calibration factor, in terms of units of electrical output (volts, amperes, etc.) per unit of the physical input parameter (pressure, acceleration, distance, etc.). In general, this includes both magnitude and phase information and is a complex quantity. The fundamental units provide a fixed reference, which is essential as it allows measurements, including calibrations, to be compared—measurements, which could have been made by different people, in different locations, and under different conditions. The units must be referred to in a known and agreed way that is well defined and monitored on an international basis in organizations like BIPM (Bureau International des Poids et Mesures). The accuracy of the calibration must also be known, that is, the device and method used to calibrate an accelerometer must perform the calibration with a known uncertainty.

If these conditions are fulfilled, the calibration is called traceable. It is important to note that traceability is not in itself an indication of high accuracy, but if the uncertainty is known, the calibration can then be compared with other valid measurements. Therefore, a calibration is not useful, unless the associated uncertainty is known. Chapter 53 has more details about traceability.

3 CALIBRATION HIERARCHY

To avoid the necessity for carrying out absolute (i.e., with direct link to the fundamental quantities) calibrations of each individual transducer, a hierarchy of reference standard transducers is established. International traceability and verification of uncertainties is obtained by performing international key comparisons of reference standard transducers between the national metrology institutes (NMIs) as required by the Consultative Committee for Acoustics, Ultrasound and Vibration (CCAUV) under the International Bureau of Weights and Measures (BIPM). Regionally key comparisons including at least one NMI are used to ensure that the uncertainties stated are fulfilled. Chapter 53 has more details about calibration hierarchy.

4 GENERAL MEASUREMENT PRINCIPLES

4.1 Description of Motion

To describe fully any motion of a solid body three linear and three rotational degrees of freedom need to be described. This makes vibration measurement and calibration different from the sound pressure, which is a parameter describing the properties at a point with only one degree of freedom. For measurement and calibration purposes it is normally desirable to create and measure only one degree of freedom at one time.

4.2 Motion Measurement

There are two basically different ways of measuring motion:

1. *Relative* measurement between two points, where the motion of one of the points is considered sufficiently well known or unimportant
2. *Absolute* measurement with respect to an inertial system

An example of the first type is the motion of a shaft relative to the bearing, where the absolute motion often is less important. The second type of measurements uses practically only so-called seismic (or mass–spring) instruments, which use an internal seismic mass as reference.

4.3 Relative Methods

A number of different principles are used to make relative measurements, some of which can also be used internally for seismic transducers. These methods

comprise capacitive, inductive, and reductive methods, but for calibration purposes a discussion of the most important methods follows.

Interferometric Methods Today the most widely used method to calibrate vibration transducers with high accuracy is the laser interferometric method. Several techniques exist, but basically a very well-defined laser wavelength is used as a gauge to measure the displacement. Often simple fringe counting can be used to determine the vibration amplitude with high accuracy.

Doppler Effect In interferometers and other similar instruments the Doppler effect is used directly to measure velocity. The basic physical law for wave propagation tells us that a wave reflected from an object moving with a velocity v relative to our combined transmitter and receiver will be frequency shifted according to the formula

$$\Delta f = \frac{2v}{\lambda}$$

where λ is the wavelength of the wave used. This may range from low-frequency sound in the metre range over radar in the centimetre range to lasers with less than 1 μm wavelength. For vibration measurements the use of lasers is increasing due to the development of well-suited inexpensive lasers and detectors.

4.4 Physical Principles Used for Absolute Measurements

All the transducers used for absolute measurements are using a seismic mass as built-in reference, and many different methods can be used for detection of the relative motion between the mass and the housing. To get a good feeling for what happens inside a seismic transducer, the model shown in Fig. 1 is used, where k is the stiffness of the spring and c is the damping. The ratio between the motion amplitude of the moving part and the relative motion of the mass with respect to the

Figure 1 Seismic transducer model.

housing can be described in magnitude and phase by the formulas

$$R = \frac{(\omega/\omega_r)^2}{\sqrt{[1 - (\omega/\omega_r)^2]^2 + [2d(\omega/\omega_r)]^2}} \quad \text{and}$$

$$\theta = \tan^{-1} \frac{2d(\omega/\omega_r)}{1 - (\omega/\omega_r)^2}$$

where d is the fraction of critical damping ($c = 2\sqrt{km} = 2m\omega_r$) and $\omega_r = \sqrt{k/m}$ is the resonance angular frequency. Some typical curves showing the resulting internal relative displacements relative to different input parameters are shown in Fig. 2.

It is seen that the relation between input acceleration and relative displacement is close to unity (better than 10%) up to about one third of the resonance frequency for lightly damped transducers. The phase shift is less than half a degree in the same range. For damped transducers the range can be extended to 0.7 times the resonance frequency at the expense of a phase shift of up to 60°.

For acceleration-sensitive transducers with high resonance frequencies (>10 kHz) the damping is normally very low and the spring very stiff. For lower resonance frequencies the amplification at resonance tends to make transducers very fragile, and therefore they are often damped by air or silicone oil.

If the resonance frequency is made very low, that is, in the range 1 to 50 Hz, then the mass will remain virtually fixed in space while the housing will move together with the structure at frequencies well above resonance. This situation is shown on the third graph in Fig. 2, indicating a numerically close to unity relation between displacements when the frequency is above two to three times the resonance frequency. In most cases the transducers, mostly referred to as velocity pickups, but also including seismometers, are damped, giving large phase errors up to more than 10 times the resonance frequency.

5 VIBRATION AND SHOCK TRANSDUCERS

5.1 Standards

In contrast to the situation for microphones there are no international standards for the shape of or output from vibration transducers. However, a few properties have become common in industry for mid-size general-purpose accelerometers. The common mounting thread is 10-32 UNF and the common connector uses the same thread and is in general referred to as a 10-32-microdot connector after the manufacturer introducing this type of connectors. Most transducers using built-in electronics work with a constant-current supply on the same line as the signal. The common way of doing this is to use a 24-V supply with a constant-current diode in series. The diode gives between 4 and 20 mA current (the higher the longer cables to be driven) and the transducer delivers the vibration signal as an oscillating voltage around a constant bias of 8 to 12 V.

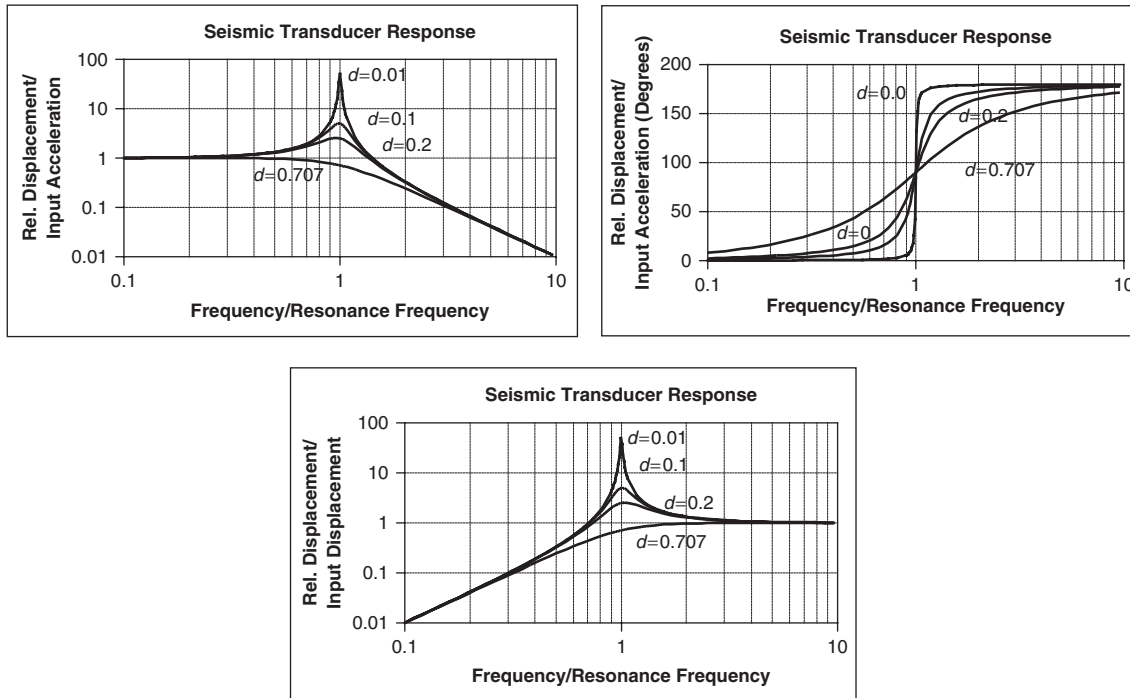

Figure 2 Internal relative displacements relative to input parameters for seismic transducers.

Another area that lacks standards is the influence of the transducer on the measured parameter. The presence of the microphone alters the sound pressure measured in front of the microphone. Therefore free-field corrections are used. The presence of an accelerometer alters the vibration of the structure on which it is mounted. The stiffness and mass of the structure (i.e., its mechanical impedance) changes the mounted resonance frequency of the transducer. These phenomena will have to be taken into account by the users, but standards for doing this in the same way are not available. Guidelines for mounting of transducers can be found in Ref. 1.

5.2 Vibration Signal Types

The motion, which is the object of measurement in any measurement setup, can be described by various parameters. First of all the directional and rotational properties of the motion need to be known. For calibration it is normally desirable to have only one degree of freedom at one time, and most transducers are also only sensitive along or around one axis. In special cases transducers can have properties where the signal along one axis have great influence on the response along another axis. In such cases calibration using multi-axis excitation can be useful, but this is quite complicated to perform and only done at specialized laboratories and at relatively low frequencies. Even if such information is available, it does not mean that the transducer alone can be used to characterize the

motion. It can normally only be used to estimate errors. If information about the critical axis input is available from another transducer, this might be used to correct the measurements, but systems doing so are very rare.

For the remaining part of the chapter we are only treating rectilinear motion along or rotational motion around the so-called sensitive axis of a transducer. For calibration normally only two different types of signals along or around the sensitive axis are used, stationary vibration signals (sinusoidal or random) or transients normally referred to as shocks. Many transducers can be calibrated by both methods and used for both types of signals, but the calibration methods differ considerably.

5.3 Transducer Sensitivity

Apart from very specialized transducers giving frequency-modulated or optical outputs the outputs from the transducers are voltage, current, or charge signals proportional to acceleration, velocity, or displacement. Some transducers have intrinsic low-impedance output or built-in electronics providing suitable electrical output when the correct power supply is used. For transducers with high-impedance output a preamplifier or conditioner will normally be needed.

5.4 Preamplifiers

For the large fraction of stable and well-proven accelerometers based on piezoelectric ceramics or

quartz without built-in electronics, it is imperative to use a suitable preamplifier/conditioner to get reliable results in calibration. The output impedance is basically a capacitance varying from a few picofarads to several nanofarads. This implies that the output voltage and the lower limiting frequency will vary according to the capacitance of the cable used, the input impedance of the amplifier, and the leakage resistance of the cable and transducer. This makes the use of voltage preamplifiers "microphone style" impractical. The better solution for such transducers is to use a so-called charge amplifier. The charge amplifier is a virtual short-circuit of the transducer through which the current is integrated giving an output proportional to the generated charge, usually expressed in picocoulombs. (Note: The unit coulomb is defined as ampere times seconds corresponding to the integration of current.) This gives a result practically independent of cable capacitance and leakage resistance. For calibration purposes the properties in the form of the gain (normally expressed as mV/pC) as a function of frequency will have to be known. Frequency ranges are often from a fraction of a hertz to 100 kHz with gains from -40 to 80 dB relative to 1 mV/pC. Many charge amplifiers have a range of high- and low-pass filters, and some have facilities for analog integration to give outputs proportional to velocity or displacement with an accelerometer at the input.

For the transducers using bridge-type sensitive elements, for example, the so-called piezoresistive (semiconductor strain gauge) transducers, a well-controlled supply of 1 to 10 V is needed. Their output is proportional to the excitation voltage. These transducers have the property that they respond to a constant acceleration. This permits special calibration methods (e.g., based on earth's gravity) to be used.

6 CALIBRATION METHODS

6.1 On-site Calibration Methods

When setting up larger measurement systems, it is good practice to check that the different transducer channels are set up correctly. Depending on the available data and the total uncertainty for each channel, a small reference vibration source can be used either for calibration of the channel or as a check of the proper function of the channel. This is performed using so called calibrators. Their use is described in the International Organization for Standardization (ISO) standard ISO 16063-21.²

Calibrators or Vibration Reference Sources

These are small, handy, completely self-contained vibration reference sources intended for rapid calibration and checking of vibration measuring, monitoring, and recording systems. Often an acceleration level of 10 m s^{-2} at a frequency of 159.15 Hz ($\omega = 1000 \text{ rad s}^{-1}$) is used, permitting the reference signal to be used also for velocity and displacement calibration at 10 mm s^{-1} and $10 \text{ }\mu\text{m}$, respectively. An example of the cross section of such a device is shown in Fig. 3. It shows the internal construction including an accelerometer that is used in a closed loop to maintain the defined level independent of the load and the support of the exciter (the relative motion between the body of the exciter and the moving element varies depending on the load and support of the exciter). The attainable uncertainty is typically 3 to 5% on the generated vibration magnitude.

If the requirements for a calibration are limited and suitable conditioning and readout instruments are available, a calibration can be performed at the vibration frequency and magnitude available from the exciter.

Figure 3 Cross section of calibration exciter. (Courtesy Brüel & Kjær, Sound & Vibration Measurement.)

Figure 4 Example of a measuring system for vibration calibration by comparison to a reference transducer. (Adapted from ISO 16063-21.)

6.2 Calibration by Earth's Gravitation

For DC responding transducers the local gravitational constant can be used to give very accurate calibrations. By letting the transducer's sensitive axis be aligned with gravity, measure the DC output and then turn it exactly 180° and measure again. The difference, which is twice the gravitational constant (close to $2g$), and its DC sensitivity can then be determined with quite high accuracy. The method is described in Ref. 3.

6.3 Calibration Service Methods

By far the largest number of transducer calibrations is made by what could be described as calibration service centers, ranging from the initial calibration at a production line over manufacturers' service centers to independent calibration centers and larger users' internal calibration departments.

Comparison Methods, Vibration The methods used are nearly always a comparison to a reference transducer supplied with a traceable calibration from, for example, a national metrology institute. This method of applying an exciter and vibration excitation is the most common method used to calibrate vibration

transducers over a frequency range. It is described in Ref. 2.

The standard provides detailed procedures for performing calibrations of rectilinear vibration transducers by comparison in the frequency range from 0.4 Hz to 10 kHz. The principle is shown in Fig. 4. An exciter is driven from a generator through a power amplifier. The moving element of the exciter is transmitting the generated motion to the two transducers mounted on top of it. The linear vibration generated at the common interface of the transducers is measured by the reference transducer and by the transducer to be calibrated. This is mounted firmly on the top of the reference or on a fixture containing the reference. In the case of stud-mounted transducers, a thin film of light oil, wax, or grease should be used between the mounting surfaces of the transducer(s) and exciter, particularly in the case of calibrations performed at high frequencies.¹ The two outputs are conditioned if necessary and compared. The measured ratio of their outputs reflects the ratio of their sensitivities when any amplification in the conditioners is taken into account. The simplest setup uses only one voltmeter and a selector. If the vibration magnitude is stable, this gives very precise calibrations also without absolute calibration of the voltmeter.

Table 1 Uncertainties for Typical Transducer Using Different Methods

	Frequency Range	160 Hz	> 2 to 10 Hz	> 10 Hz to 2 kHz	> 2 to 4 kHz	> 4 to 7 kHz	> 7 to 10 kHz
Method	Reference calibration						
Vibration source	160-Hz calibrator	3–5					
Comparison best attainable	Best NMI multipoint calibration	0.4	0.4	0.5	0.5	0.8	1.0
Comparison typical	160 Hz ref. calibration	0.6	0.7	0.7	0.9	1.2	1.8
Best NMI laser interferometry on good reference transducer		0.2	0.2	0.2	0.3	0.4	0.4

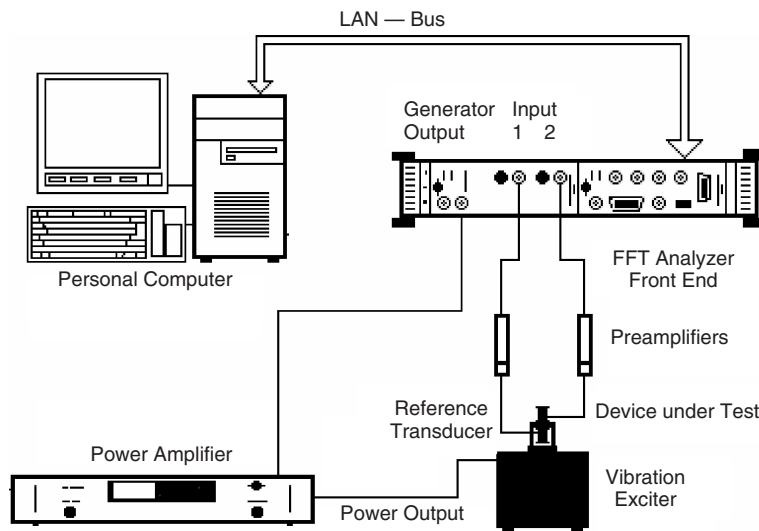

Only the sensitivity of the reference and the gain of the conditioners are needed. If phase is required, a phase meter can be added. An oscilloscope is practical for observing the process but is not a requirement. If transducers responding to different vibration parameters (e.g., a reference responding to acceleration and a velocity pickup to be calibrated) are tested, the distortion can be important and needs to be measured to evaluate the uncertainty. However, it is normally not needed for each measurement but only for getting data for the uncertainty calculations.

The standard contains detailed instructions for calculation of the total expanded uncertainties for such systems. The most important parts are the uncertainty of the reference, the determination of the ratio of the two outputs, and last but not least the effect of transverse, rocking, and bending motion combined with the transverse sensitivity of the transducers. The latter is often underestimated due to lack of information about the exciters used and the transverse sensitivity of the transducers. It is, for example, not unusual to find transverse and rocking motion in the order of 25% or more in certain frequency ranges. An example

of typical and best attainable uncertainties on a typical transducer on “spring guided” exciters is given in Table 1. The frequency range will normally require more than one exciter and the transverse sensitivity on the transducer is given as 5% maximum at low frequencies increasing to 10% at 10 kHz. The values are total estimated uncertainties for a coverage factor $k = 2$. They are somewhat lower than the values given in the standards that have rather conservative values.

In modern systems a two-channel fast Fourier transform (FFT) analyzer with a generator can replace most of the individual instruments, as shown in Fig. 5. In this case magnitude and phase are obtained automatically and distortion is unimportant but can also easily be measured.

Comparison Methods, Shock In general, the vibration exciters used can normally not deliver more than 1000 m s^{-2} (100g), and therefore shock methods are used to obtain peak magnitudes of $100,000 \text{ m s}^{-2}$ (10,000g) to check linearity of transducers. A comprehensive standard was recently published: ISO 16063-22:2005, Methods for the Calibration of

**Figure 5** Example of vibration transducer calibration system used for comparison to a reference transducer.

Figure 6 Principle of interferometer used for ratio counting.

Vibration and Shock Transducers—Part 22: Shock Calibration by Comparison to a Reference Transducer. The main difference from vibration calibration is that an impulsive excitation is used, mostly obtained by letting a piston or hammer mechanism hit an anvil on which the reference and unknown transducer is mounted. The peak magnitudes of the two time records are determined, and their ratio gives the ratio of the sensitivities just like for vibration. Often curve-fitting techniques are used to get a good determination of the maximum. FFT analysis can also be used to give a frequency response within the range of frequencies contained in the shock pulse spectrum.

Comparison Methods, Angular Vibration When angular vibration is measured, methods very similar to linear vibration can be used. The only difference being that the exciter will produce an angular vibration. A standard in the ISO 16063 series is under preparation as Part 23: Angular Vibration Calibration by Comparison to a Reference Transducer.

6.4 Methods of National Metrology Institutes

At the NMIs a number of primary calibration methods are used. The goal is to get the unit [e.g., $\text{V}/(\text{m s}^{-2})$] determined by means as close to the fundamental units (V, m, and s) as possible. The methods are not limited to the NMIs, as other laboratories might use them if they have the need.

Primary Vibration Calibration Methods The most common method used today is the primary vibration calibration by laser interferometry. It is

described in Ref. 4. A reciprocity technique based on the same fundamental principles as for microphones has been used since the 1950s but is now less used because it is more complicated than the laser interferometry. The reciprocity method is described in Ref. 5.

A typical setup for vibration calibration by laser interferometry is shown in Fig. 6. It illustrates method 1 of the 3 methods described in the standard. This is the so-called fringe-counting method. The laser beam from a HeNe laser working in the TEM00 mode gives a beam with sufficient coherence length and well-defined wavelength. The beam is divided into two by a beam splitter. One beam reaches the fixed mirror and is reflected back onto the detector, the other is reflected from the surface of the moving accelerometer (or a mirror block attached to it) and then deflected by the beam splitter to the detector where it interferes with the other part. A motion of $\lambda/4$ will change the path length by $\lambda/2$ and thereby the phase between the two beams by 180° . This leads to the following relationship between the number of intensity shifts or fringes per vibration period R_f and the sinusoidal acceleration amplitude \hat{a} :

$$R_f = \frac{8\hat{a}}{\omega\lambda} = \frac{8a_{\text{rms}}\sqrt{2}}{(2\pi f)^2\lambda}$$

where ω = angular vibration frequency

f = vibration frequency

λ = wavelength of the laser beam

a_{rms} = root-mean-square (rms) value of the sinusoidal acceleration

By using a counter to count the fringes using the vibration frequency as reference, the ratio R_f is obtained directly. A very precise determination of the vibration amplitude is obtained by averaging over 100 or more periods. This method works well from the lowest frequencies and up to about 1000 Hz where the amplitude in the vibration only gives a few fringes.

The mathematical description of the detector signal shows that the frequency component at the vibration frequency becomes zero at certain values of the vibration amplitude given by the Bessel function of first kind and first order. This is described as method 2 in the standard, useful at frequencies from 800 Hz to 10 kHz. By varying the amplitude of the vibration, the zero points can be found as minima of the filtered detector signal and the transducer sensitivity can then be determined.

Method 3 of the standard is the so-called sine approximation method. The interferometer is now be configured to give two outputs in quadrature. These two signals will theoretically describe a point following the path of a circle if they were used to give the x and y deflections of an oscilloscope. Mathematically, the angle $\hat{\phi}$ to the point on the circle, found as the \arctan of B/A (where B and A are the y and x values found for the point on the circle) gives the displacement (relative to λ) leading to the relationship

$$\hat{a} = \pi \lambda f^2 \hat{\phi}$$

where $\hat{\phi}$ is the modulation phase amplitude, the other symbols as above. This technique requires high-frequency analog-to-digital conversion of the detector signals and has, therefore, only been possible at reasonable cost recently. It can be used over the full frequency range provided a sufficient amount of fast memory is available and that conversion frequencies sufficient for the desired velocity can be used. It can also be used to determine the phase shift of the transducers.

For DC responding transducers primary DC calibration can be performed by different centrifuge-based methods. These are described in Refs. 6 and 7. The large installations needed imply that these methods are normally only used for inertial guidance-type transducers. These are considered outside the scope of this handbook.

Primary Shock Calibration Methods Although older methods, using velocity determination by two light beams being cut, might still be useful, the modern way is described in Ref. 8. It is basically identical to method 3 used for primary vibration but will require wider bandwidth if the full range of shock pulses is to be measured. The range covers shocks with peak accelerations of 100 to 100,000 m s^{-2} . The shocks are generated by the same methods as used for comparison calibration. The attainable uncertainty is 1% at a reference peak value of 1000 m s^{-2} and 2 ms duration and up to 2% at other values.

6.5 Transducer Test Methods

Environmental Testing For selection of transducers for specific measurement tasks it can be important

to know the performance under special environmental conditions. For these tests a number of ISO standards are available, some of them under revision:

- ISO 5347-11:1993, Part 11: Testing of Transverse Vibration Sensitivity (to become ISO 16063-31, Methods for the Calibration of Vibration and Shock Transducers—Part 31: Testing of Transverse Vibration Sensitivity)
 - ISO 5347-12:1993, Part 12: Testing of Transverse Shock Sensitivity
 - ISO 5347-13:1993, Part 13: Testing of Base Strain Sensitivity
 - ISO 5347-14:1993, Part 14: Resonance Frequency Testing of Undamped Accelerometers on a Steel Block
 - ISO 5347-15:1993, Part 15: Testing of Acoustic Sensitivity
 - ISO 5347-16:1993, Part 16: Testing of Torque Sensitivity
 - ISO 5347-17:1993, Part 17: Testing of Fixed Temperature Sensitivity
 - ISO 5347-18:1993, Part 18: Testing of Transient Temperature Sensitivity
 - ISO 5347-19:1993, Part 19: Testing of Magnetic Field Sensitivity
- Parts 12–19 of ISO 5347 were confirmed in 2004.

Only the concept and testing of transverse vibration sensitivity shall be described briefly as it is important for most calibrations. Figure 7 illustrates the concept. For any vibration transducer there exists one axis that provides maximum response to a vibration input. Due to small imperfections in the mechanical alignment and, for example, polarization direction of the piezoelectric elements in piezoelectric accelerometers, this axis is not perpendicular to the mounting surface. Therefore, as shown in the figure the maximum sensitivity vector will have a projection onto the plane of the mounting surface. This projection is referred to as the maximum transverse sensitivity of the transducer, and its value is normally stated in the calibration chart. The sensitivity to vibration in directions in the plane of mounting can be described as a figure of eight (i.e., two circles touching in a point). The direction of minimum transverse sensitivity is indicated on some transducers. This allows the transducer to be aligned in order to give minimum sensitivity to a specific direction of vibration. The testing has typically been made by low-frequency long-stroke (> 25 mm) sliding tables with built-in turntables. The motion in the sensitive direction shall be below 0.1% of the in-plane motion. Operating the turntable permits the determination of minimum direction and maximum sensitivity. The frequencies used are typically 10 to 50 Hz. For higher frequencies vibrating long bars are used, excited by two perpendicular exciters for which the relative phase can be varied to give the desired motion. As mentioned when discussing vibration signal types, some transducers (especially “cantilever constructions”) have transverse sensitivities depending on the vibration in the main axis direction. To give a complete description of

Figure 7 Transducer transverse sensitivity.

their behavior special setups are needed giving multi-axis excitation.⁹

CHAPTER 53

METROLOGY AND TRACEABILITY OF VIBRATION AND SHOCK MEASUREMENTS

Hans-Jürgen von Martens
Physikalisch-Technische Bundesanstalt (PTB)
Braunschweig and Berlin, Germany

1 INTRODUCTION

Traceability to the International System of Units (SI) is increasingly required for vibration and shock measurements as specified in international standards, recommendations, and regulations to ensure product quality, health, and safety. Metrology, known as the science of measurement, includes all aspects both theoretical and practical with reference to measurements, whatever their uncertainty. It is important to be aware of the metrological aspects of establishing traceability for measurements of rectilinear and angular motion quantities, including the evaluation of measurement uncertainty. New and upgraded ISO (International Organization for Standardization) standards provide a variety of calibration methods with respect to their suitability for ensuring traceability. Advanced traceability systems provide the generation and highly accurate measurement of rectilinear vibration and shock motion, as well as angular motion. National measurement standards in most countries constitute the top level of the traceability chain. Specifically developed national measurement standards are directly accessible for highly accurate measurements of metrological characteristics of rectilinear and angular transducers and vibrometers.

2 VIBRATION AND SHOCK FROM THE VIEW OF METROLOGY

2.1 Realization of the SI Units of Motion Quantities

The terms *vibration* and *shock* are defined as special variations with time of the magnitude of a quantity, which is descriptive of the motion or position of a mechanical system (cf. ISO 2041¹). The physical quantities widely used to describe vibration and shock motion in different applications are rectilinear acceleration, velocity, displacement and angular acceleration, angular velocity, and rotation angle (cf. Table 1). From the viewpoint of metrology, the units and associated scales of the six motion quantities have to be realized and disseminated with appropriate time dependencies (preferably sinusoidal and shock-shaped time histories).

To realize the SI units and associated scales of motion quantities such as acceleration and angular acceleration, adequate national measurement standards are needed. A *national (measurement) standard* is a standard recognized by a national decision to serve, in a country, as the basis for assigning values to other standards of the quantity concerned.² Such other standards are *primary standards*, *secondary standards*,

reference standards, *working standards*, and *transfer standards* (for definitions, see Ref. 2). The variety of motion quantities and their time histories to be realized and disseminated cannot be covered by a single standard device. An ensemble of seven national measurement standards covering the realization and dissemination of the six motion quantities in wide parameter ranges and with the highest accuracy achieved so far is described in Section 5.

2.2 Dissemination of the SI Units of Motion Quantities

To disseminate the units and associated scales of motion quantities, calibrations of standard transducers or measuring instruments (see Section 2.1) are carried out. Three typical calibration situations (measuring instrument, calibrator, transducer) are shown in Fig. 1. In Fig. 1a the standard device consists of a generator, which produces the measurand x , and a standard measuring instrument, which measures x . The reading of the measuring instrument to be calibrated when supplied with the input x is compared with the indication of the standard device. The same arrangement is shown in Fig. 1b, however, standard and object to be calibrated have changed their role: The object to be calibrated is a calibrator consisting of generator and measuring instrument, and the standard is a single measuring instrument. In this case, the calibrator generates a specified quantity x that is indicated by the associated instrument. The reading is compared with the reading of the standard measuring instrument. The block diagram in Fig. 1c shows that the calibration of a transducer is similar to that of a measuring instrument, except that the transducer output signal must be measured by an additional standard measuring instrument [e.g., a root-mean-square (rms) voltmeter].

All three arrangements have in common that the generator produces disturbing quantities $z_i(G)$, in addition to the measurand (e.g., a purely sinusoidal vibration). These disturbing quantities $z_i(G)$ act on both measuring instruments (e.g. harmonics from nonlinear distortion). Other disturbing quantities $z_i(E)$ originate in the environment (e.g., temperature) and may also have correlated effects on the two instruments.

The variety of disturbing effects to be considered in the uncertainty evaluation will be demonstrated in Section 6. In the uncertainty evaluations, no distinction will any longer be made between $z_i(G)$ and $z_i(E)$, which will be referred to as influence quantities z_i .

Table 1 Rectilinear and Angular Motion Quantities (Sinusoidal, Shock-Shaped and Other Dependencies on Time)

Motion			Dependence on Time	
Direction	Quantity	Unit	General	Sinusoidal
Linear	Displacement s	m	$s(t)$	$s(t) = \hat{s} \cos(\omega t + \varphi_s)$
	Velocity v	m/s	$v(t) = \frac{ds}{dt}$	$v(t) = \hat{v} \cos(\omega t + \varphi_v), \hat{v} = \omega \hat{s}, \varphi_v = \varphi_s + \frac{\pi}{2}$
	Acceleration a	m/s ²	$a(t) = \frac{d^2s}{dt^2}$	$a(t) = \hat{a} \cos(\omega t + \varphi_a), \hat{a} = \omega^2 \hat{s}, \varphi_a = \varphi_s + \pi$
Angular	Rotation angle Φ	rad	$\Phi(t)$	$\Phi(t) = \hat{\Phi} \cos(\omega t + \varphi_\Phi)$
	Angular velocity Ω	rad/s	$\Omega(t) = \frac{d\Phi}{dt}$	$\Omega(t) = \hat{\Omega} \cos(\omega t + \varphi_\Omega), \hat{\Omega} = \omega \hat{\Phi}, \varphi_\Omega = \varphi_\Phi + \frac{\pi}{2}$
	Angular acceleration α	rad/s ²	$\alpha(t) = \frac{d^2\Phi}{dt^2}$	$\alpha(t) = \hat{\alpha} \cos(\omega t + \varphi_\alpha), \hat{\alpha} = \omega^2 \hat{\Phi}, \varphi_\alpha = \varphi_\Phi + \pi$

3 TRACEABILITY CONCEPTS

3.1 Traceability of Vibration and Shock Measurements

Traceability is defined² as the property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties. An unbroken chain of comparisons is called a *traceability chain*. No international measurement standard exists in the area of vibration and shock measurements. However, several countries—through their *national metrology institutes* (NMIs) and accreditation bodies—have related the measurements of rectilinear and angular motion quantities to the *national measurement standards* of another country after the latter had verified the best accuracy of calibrations within the framework of international and regional comparisons (see Section 5). The above definition of traceability given in Ref. 2 is a general one. For vibration and shock measurements, specific traceability concepts have been established, which will be described and discussed in the following.

3.2 Requirements on Traceability

The SI units for physical quantities, such as metre per second squared (m/s²) for the quantity of acceleration, are realized by NMIs and disseminated to external clients through calibrations (cf. Fig. 2). The metrological infrastructure of a country is formed by accredited and nonaccredited calibration laboratories. All calibration laboratories (including NMIs) have to comply with the ISO/IEC Standard 17025³ (IEC is the International Electrotechnical Commission). Section 5.6, Measurement Traceability, of this international standard gives specific requirements for establishing the traceability of measurement standards and measuring instruments to the SI units through an unbroken chain of calibrations or comparisons. The calibration certificates issued by calibration laboratories have to state the measurement results, including the measurement uncertainty and/or a statement of conformity with an equivalent metrological specification. The uncertainty

of measurement is to be evaluated and expressed in accordance with the *ISO Guide*.⁴ To ensure compliance of the units realized by the NMIs, within well-specified uncertainties in accordance with their definition in the SI, key comparisons are carried out. Key comparisons carried out in the area of vibration organized under the auspices of the *Consultative Committee for Acoustics, Ultrasound and Vibration (CCAUV)* include a limited number of NMIs worldwide (e.g., 12 NMIs in CCAUV.V-K1, see Section 4.4). The key comparison reference values (KCRVs) as specified by the International Committee for Weights and Measures (CIPM) key comparisons are disseminated through various regional key comparisons to a great number of NMIs within the regional metrology organizations (RMOs), in particular the Asia Pacific Metrology Programme (APMP), Euro-Asian Cooperation of National Metrology Institutions (COOMET), European Collaboration in Measurement Standards (EUROMET), Southern African Development Community Cooperation in Measurement Traceability (SADCMET), and Sistema Inter-Americano de Metrologia (SIM, Inter-American System of Metrology).

3.3 Traceability to Primary Methodologies

From the definition of traceability and the explanations given above, it should be clear that the chain of calibrations providing traceability has its origin in adequate national measurement standards.

One traceability system widely used is based on primary vibration calibration of an accelerometer standard by laser interferometry at the NMI level and secondary vibration calibration by the comparison method at the level of accredited calibration laboratories (cf. Fig. 2). After primary calibration, this accelerometer standard can be used in a calibration laboratory, both the accelerometer standard (reference accelerometer) and the transducer to be calibrated being subjected to the same motion and their output signals being compared. If that transducer is a working standard, it is used afterwards in a nonaccredited laboratory for the calibration of working transducers or vibrometers by comparison, too. The upgraded documentary standards recently developed for vibration calibration by laser

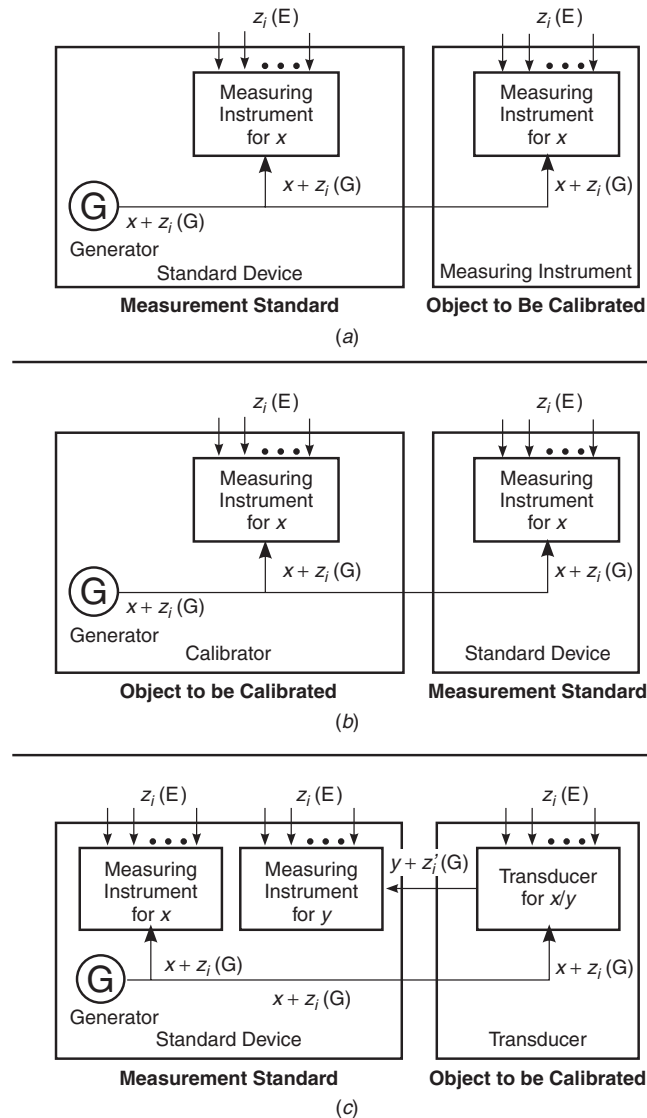

Figure 1 Block schemes of typical calibration setups with measurand x and influence quantities z_i : (a) vibration measurement instrument, (b) vibration calibrator, and (c) transducer (e.g., accelerometer).

interferometry (ISO 16063-11⁵) and calibration by comparison to a reference transducer (ISO 16063-21⁶) reflect the need for calibration in the frequency range, which is representative for the conditions of application of the reference transducer or working transducer (specified frequency range 0.4 Hz to 10 kHz).

Vibration calibration is not representative for the behavior of a transducer used for shock measurements. As a normative basis to ensure traceability for shock acceleration measurements, the new standards ISO 16063-13⁷ for primary shock calibration by laser interferometry and ISO 16063-22⁸ for shock calibration by

comparison to a reference transducer have recently been developed. The standard⁸ specifies to which degree and with which consequences a primary shock calibration of a reference transducer can be dispensed with:

1. "If the reference transducer has proved to be linear, the primary shock calibration may be replaced by primary vibration calibration in accordance with ISO 16063-11 or ISO 16063-12."^{5,9}
2. "Hopkinson bar shock calibrators have operational ranges of high accelerations (peak values 1 km/s² to 2000 km/s²), which may be used to

Figure 2 General traceability chain and application to vibration and shock measurements.

evaluate the performance of transducers. This part of ISO 16063 specifies the range from 100 m/s^2 to 100 km/s^2 , which has reference to primary methodologies (ISO 16063-13). Larger accelerations (peak values) and shorter pulse durations are possible but without reference to primary methodologies.”⁸

The term *primary methodologies* is used above as reference to those implemented ISO standard methods that are *adequate* for the primary calibration of standard transducers. This underlines that other primary calibration methods specified in ISO 5347-5:1993 (Calibration by Earth’s Gravitation), 5347-7:1993 (Primary Calibration by Centrifuge), and 5347-8:1993 (Primary Calibration by Dual Centrifuge) are *not adequate* for transducers intended to be used for measurements of shock-shaped or other time dependencies outside the scopes of these standards, and vice versa.

It is sometimes assumed that traceability to the SI unit of acceleration or other motion quantities can be established by any calibration laboratory by implementation of a primary calibration method (e.g., reciprocity method or laser interferometry in accordance with the relevant ISO standard), without link-up to an NMI. Primary calibration methods may well be used in an accredited or a nonaccredited calibration laboratory for some reasons. However, the implementation of a *primary calibration method* specified in the ISO standards does not necessarily lead to a *primary standard* which is by definition² a standard that is designed or widely acknowledged as having the highest metrological qualities and whose value is accepted

without reference to other standards of the quantity concerned. Such primary standards (national measurement standards) are usually established only in the NMI of the respective country by implementation of ISO primary calibration methods. The CIPM key comparison CCAUV.V-K1 revealed that the compliance with given uncertainty limits of calibration equipment used in calibration laboratories (primary calibration included) can only be verified by linkup to appropriate national measurement standards, which have specified uncertainties that have been validated in international or regional key comparisons or supplementary comparisons performed under the auspices of the *International Bureau of Weight and Measures (BIPM)* and the associated Consultative Committee, CCAUV: All 12 participating laboratories have used laser interferometry in accordance with ISO 16063-11⁵ and demonstrated good results in the calibration of one of the two transfer standards, which was a reference accelerometer of back-to-back design, whose reference surface (top surface) was accessible to the laser light beam. However, for the other reference accelerometer that was of single-ended design, the calibration results of several laboratories showed significant systematic deviations (at 5 kHz greater than 1% up to 6%) due to significant relative motion in the kilohertz range between the laser light spot and the accelerometer reference surface (mounting surface).¹⁰ For the variety of sources of error and uncertainty components to be considered in calibrations, see Section 6.

3.4 Traceability to National Measurement Standards

This subsection combines the general requirement of traceability to primary methodologies (see Section 3.3)

with the objective to provide motion quantities with adequate time histories by the national measurement standards.^{11,12} Traceability for vibration and shock measurements can be ensured by generating at the NMI level the three linear and three angular motion quantities (cf. Table 1) with sinusoidal, shock-shaped, and other, user-defined time histories and by measuring them by laser interferometry. The latest developments in laser interferometry have made it possible to establish a uniform methodology for primary measurement, covering the variety of motion quantities, sinusoidal and shock-shaped time dependencies, and wide parameter ranges. The traceability chain described in Section 5 realizes and disseminates the units of the respective physical quantities at such time dependencies that reproduce, during calibration of any transducer (e.g., accelerometer) or measuring instrument (e.g., laser vibrometer), as closely as possible the conditions of use after calibration (i.e., shock measurement in the peak value acceleration range of 1 km/s² to 50 km/s² at defined shock shapes and pulse durations).^{13,14}

3.5 Option of Direct Access to National Measurement Standards

As the measurement and calibration capabilities available at the NMI level go, in some cases, far beyond those available at lower levels of the traceability chain (i.e., in accredited calibration services and industrial calibration laboratories), the national measurement standards may be used directly to meet special demands from industry and elsewhere for investigations of the dynamic behavior of transducers and measuring instruments or for their accurate dynamic calibration (for examples see Section 5).

4 ESTABLISHMENT OF TRACEABILITY

4.1 Selection of ISO Standard Methods

Under the general title *Methods for the Calibration of Vibration and Shock Pick-ups*, a standard series, ISO 5347, was issued in the period between 1987 and 1997. A revision of the ISO 5347 series, renumbered to ISO 16063, was started in 1995, focusing on the specification of upgraded and new calibration methods needed at different levels of a traceability chain for the field of vibration and shock: methods for primary vibration calibration, secondary vibration calibration, primary shock calibration, and secondary shock calibration.

For primary vibration calibration by laser interferometry at the NMI level, ISO 16063-11:1999⁵ has extended the frequency range (0.4 Hz to 10 kHz) and included absolute phase shift measurement. ISO 16063-13:2001⁷ provides interferometric primary shock calibration (100 m/s² to 100 km/s²). ISO 16063-15¹⁵ specifies primary angular vibration calibrations (magnitude and phase shift) in the frequency range from 0.4 Hz to 1.6 kHz. For rectilinear vibration and shock calibration at lower levels of the traceability chain, Parts 21 and 22 of ISO 16063 provide upgraded comparison methods, and ISO 16063-23 is the corresponding project for angular vibration calibration by comparison to a reference transducer.

4.2 Implementation of ISO Standard Methods

Hierarchies of measurement standards have been established and are operated in NMIs as well as in accredited and nonaccredited calibration laboratories, in compliance with the upgraded and new ISO standards (see Section 4.1). Most of the NMIs use commercial high-quality vibration and shock generators or even complete calibration equipment.

Alternatively, several NMIs have specifically developed vibration and shock generators (e.g., NIST Super Shaker,¹⁶ PTB rectilinear and angular motion exciters,^{13,14} see also Section 5) and laser interferometry.^{17–24} Examples of specific national measurement standards are briefly described in Section 5. For other examples, see Refs. 25 to 34.

Accredited and nonaccredited calibration laboratories are in most cases equipped with commercial calibration devices that are available from several manufacturers in compliance with the respective ISO standards. Using the ISO methods specified, national measurement standards and calibration equipment for calibration laboratories provide many new and improved calibration and measurement capabilities and thus international traceability.

4.3 Calibration and Measurement Capabilities Available

Uncertainties for different methods on typical transducers using different methods are specified in Table 1 of Chapter 52 with reference to the ISO standards and to the calibration and measurement capabilities (CMCs) published at <http://www.bipm.org>. In the following, a more detailed survey is given.

Capabilities of National Metrology Institutes

The NMIs equipped with primary and/or comparison calibration facilities have offered their CMCs in Appendix C of the Mutual Recognition Arrangement (MRA) (see <http://www.bipm.org>, Key Comparison Database). An example for the wide measurement ranges of vibration and shock parameters covered by primary calibration in an NMI using several national measurement standards is described in Section 5.

Capabilities of Accredited Calibration Laboratories

As most calibration laboratories accredited for vibration and shock measurements and calibrations (quantity of acceleration) are equipped with commercial high-quality calibration equipment, their calibration capabilities confirmed by the accreditation body of the respective country (e.g., UKAS in the United Kingdom, DKD in Germany, and NATA in Australia) also meet high demands. This is valid in particular if the reference standards of the calibration laboratory are periodically calibrated in an NMI providing high-level CMCs.

For example, the calibration capabilities of the calibration laboratories accredited by the Deutscher Kalibrierdienst (DKD) are specified at www.dkd.info. Rectilinear vibration calibrations cover frequencies from 0.4 Hz to 20 kHz (including phase calibrations

Figure 3 Results of an interlaboratory comparison of shock calibrations: method A: pendulum shock calibrator, method B: linear shock calibrator (air bearing), method C: pneumatic shock calibrator, and method D: drop ball calibrator.

up to 10 kHz), shock calibrations cover 50 m/s² to 100 km/s², and angular calibrations are available, for example, in the frequency range from 8 Hz to 100 Hz for angular velocity transducers. The accreditation for best uncertainties of 0.25% (sinusoidal) and 1% (shock acceleration) was possible because of the highly accurate primary calibrations of the laboratories' reference transducers carried out at the NMI of Germany (PTB).

4.4 Demonstration of CMCs by Comparisons

Though it might be expected that all calibration laboratories (NMIs included) establish uncertainty budgets in compliance with the *ISO Guide*,⁴ the accuracy attained can be reliably assessed only by appropriate comparison measurements. Numerous international, regional, and national comparisons performed over the last two decades have largely contributed to the recognition of systematic deviations and their sources and to prove the uncertainty statements of any laboratory. In Ref. 13, the comparisons reported in Refs. 35 to 38 are discussed in detail. The first key comparison in the area of vibration³⁹ carried out between 12 NMIs worldwide, furnished highly accurate key comparison reference values that have been disseminated to many countries by regional key comparisons within the regional metrology organizations (e.g., Ref. 40). It was demonstrated that great experience and the application of advanced techniques are

necessary to reach an expanded uncertainty (coverage factor $k = 2$) of 0.5% at a reference frequency of 160 Hz and 1% at other frequencies in the range from 1 Hz to 10 kHz in accordance with the international standard.⁵ The results and conclusions of the key comparison CCAUV.V-K1 are specified in detail in Ref. 39. In addition to the magnitude, the phase shift of the complex sensitivity of reference accelerometers has also been included in comparisons at the NMI level.⁴¹

As an example, Fig. 3 shows a result of the interlaboratory shock comparison of the DKD laboratories in Germany, performed in 2001. The relative deviations of the DKD laboratories results of the shock sensitivity of a reference accelerometer from the reference values measured at the PTB were less than 1% in all cases. This has demonstrated the reliability of the accredited best measurement uncertainty of 1%. For a European interlaboratory comparison see Ref. 42.

5 EXAMPLE OF AN ADVANCED TRACEABILITY CHAIN

5.1 Concept for Motion Generation and Measurement at the NMI Level

For the advanced state of the realization and dissemination (by primary calibration) of the units of motion quantities, the traceability chain established in Germany may be considered as a representative example^{13,14}; see www.ptb.de. An ensemble of seven different measuring standards have been developed

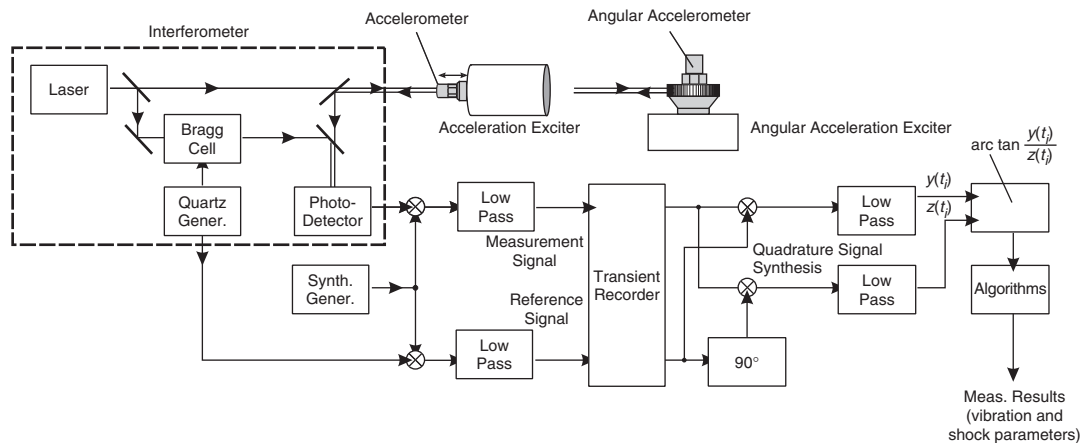

Figure 4 Generation and measurement of linear and angular motion quantities, using exciters with air bearings, heterodyne interferometers with frequency conversion, and digital data processing.

at the PTB for the realization of the units of the six motion quantities (cf. Table 1) and the primary calibration of transducers of these motion quantities. Each measuring standard consists of a rectilinear or an angular acceleration exciter, a laser interferometer with signal measuring system, a system for measuring electrical output quantities of calibration objects (voltage or charge), a supply system, and a vibration isolation system. The motion exciters have been specially designed to generate the six motion quantities rectilinearly or around a fixed axis, with sinusoidal or defined shock-shaped time dependencies.

Laser interferometry, which is the preferred primary vibration calibration method at the NMI level, has been further developed at PTB in the last years as a uniform methodology and technique for the primary measurement of translational motion quantities (e.g., acceleration) and rotational motion quantities (e.g., angular acceleration) at sinusoidal, shock-shaped, and other, user-defined time histories.^{13,43–49} Figure 4 shows the methods and techniques applicable to all the measurement standards, in accordance with ISO 16063-11⁵ (sine-approximation method), ISO 16063-13⁷ (shock signal processing; see Fig. 8), and ISO 16063-15¹⁵ (sine-approximation method), respectively. Alternatively, for special measurements and calibrations, homodyne interferometry is used in specific modifications.^{50,51}

The vibration isolation systems are specifically developed so that the reaction forces from the motion exciter are prevented from exciting any disturbing motion (e.g., resonance) in sensitive interferometer parts (e.g., beam splitter, reference reflector), and the interferometer is isolated from ground motion. Active vibration isolation control and position control is used to ensure efficient vibration isolation while keeping the interferometer adjusted.

To simulate in calibrations typical multiaxial excitation to which working transducers are frequently

exposed, a standard measuring device has been developed to simultaneously generate and precisely measure motion quantities in up to three orthogonal directions (X, Y, Z) and around a rotational axis (Z), with user-defined time histories (see Section 5.3).

The primary calibration methods and techniques developed at PTB in compliance with the ISO standards and current standardization projects are used in Germany and Europe on the basis of three agreed EUROMET projects providing traceability for sinusoidal acceleration (Project Ref. No. 198), angular acceleration (Project Ref. No. 284), and shock acceleration (Project Ref. No. 368), cf. www.EUROMET.org. Traceability is provided by primary calibrations of reference or transfer standards, which are later used in accredited calibration laboratories (calibration services) in Germany and other countries. The calibration capabilities achieved in accredited calibration laboratories are shown at www.DKD.info as an example.

5.2 Survey of National Measurement Standards Developed

The national measurement standards based on the concept of Section 5.1 are

1. Low-frequency acceleration standard 0.1 Hz to 20 Hz (sinusoidal vibration, max. displacement double amplitude 1 m, cf. Fig. 5)
2. Low-frequency acceleration standard 0.4 Hz to 63 Hz (sinusoidal vibration, max. acceleration amplitude 15 m/s²)
3. Medium-frequency acceleration standard (sinusoidal vibration, 10 Hz to 5 kHz)
4. High-frequency acceleration standard (sinusoidal vibration, 10 Hz to 20 kHz, min. displacement amplitude 1 nm; see Figs. 6 and 7)
5. Shock acceleration standard 50 m/s² to 5 km/s² (shock duration 0.8 ms to 10 ms)

Figure 5 Low-frequency acceleration measurement standard 0.1 Hz to 20 Hz.

6. Shock acceleration standard 1 km/s^2 to 100 km/s^2 (shock duration $70 \mu\text{s}$ to $300 \mu\text{s}$; cf. Fig. 8).
7. Angular acceleration standard (sinusoidal vibration, 0.4 Hz to 1 kHz)

The standard measuring devices are named acceleration standard and angular acceleration standard, respectively. However, at sinusoidal accelerations or angular accelerations free from distortion, the measurands velocity, displacement and angular velocity, and rotation angle, respectively, are generated at the same time so that, in connection with the laser interferometer, the units of the three rectilinear motion quantities (acceleration, velocity, and displacement) and of the three angular motion quantities (angular acceleration, angular velocity, and rotation angle) are realized. The measurement uncertainty stated for acceleration and angular acceleration is also valid for the two other translational or rotational motion quantities.

The amplitudes of sinusoidal accelerations, velocities, and displacements are measured with a relative measurement uncertainty of 0.1% to 0.2% at frequencies from 0.4 Hz to 20 kHz (frequency dependent). The complex sensitivity of precise accelerometers

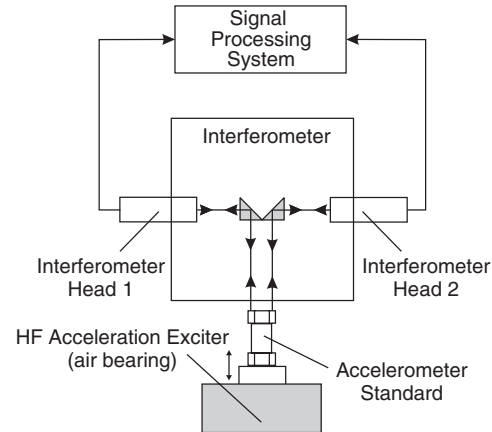

Figure 6 HF acceleration standard equipped with two-channel laser interferometry used for the calibration of accelerometers.

(reference and transfer standards) can be measured with a measurement uncertainty of 0.1% to 0.3% for the magnitude and of 0.2° to 0.5° for the phase shift in the frequency range from 0.4 Hz to 10 kHz (primary calibration in accordance with ISO 16063-11⁵). For frequencies higher than 10 kHz, a best measurement uncertainty of $\leq 1\%$ up to 20 kHz is available for the calibration of reference accelerometers. For the calibration of reference laser vibrometers in compliance with ISO 16063-11, a best measurement uncertainty of 0.1% to 0.2% at frequencies from 0.4 Hz to 20 kHz is attainable to date. The CIPM key comparison CCAUV.V-K1 revealed that the PTB has kept the extremely low expanded uncertainty $< 0.1\%$ (expanded uncertainty for coverage factor $k = 2$, see Ref. 4) at all 22 frequencies from 40 Hz to 5 kHz (one-third octave frequency series) covered by the key comparison.

For primary shock calibrations in compliance with ISO 16063-13,⁷ a best measurement uncertainty of $\leq 0.5\%$ to 1% is available at acceleration peak values from 50 km/s^2 to 100 km/s^2 . In addition to the shock

Figure 7 HF acceleration standard modified for laser vibrometer calibrations.

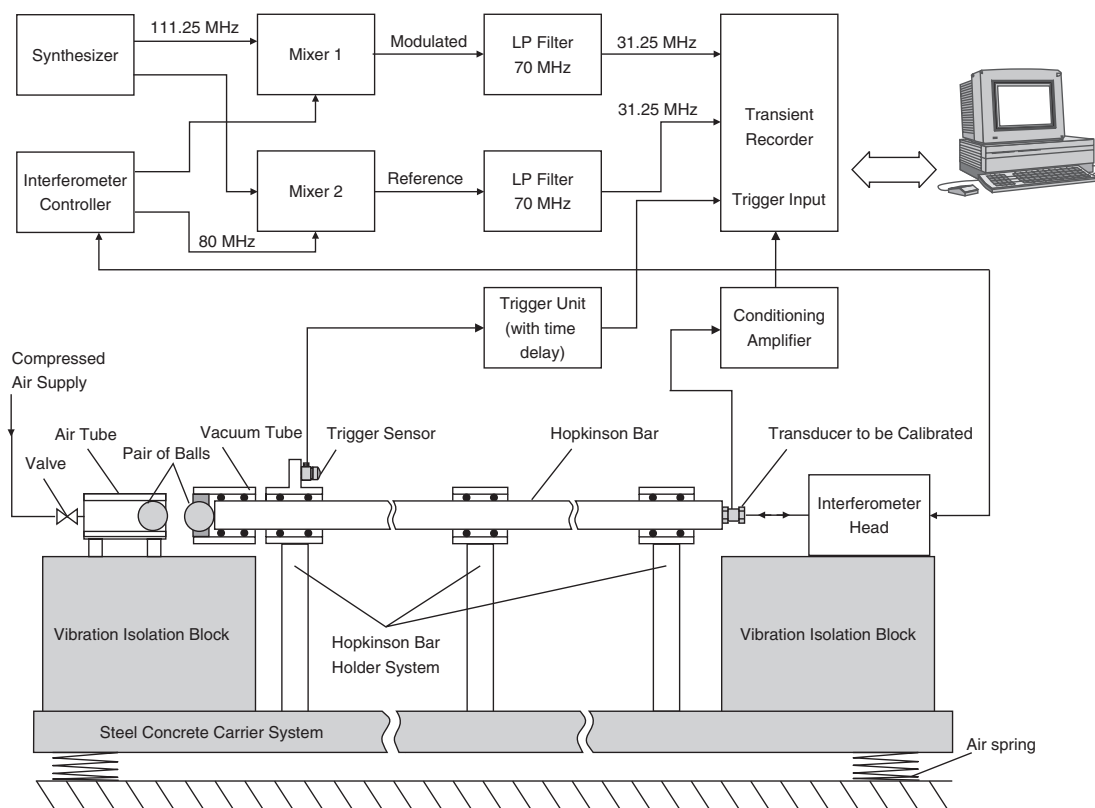

Figure 8 Shock acceleration measurement standard 1 km/s^2 to 100 km/s^2 .

sensitivity defined as the ratio of peak value of the output to peak value of the acceleration, the sensitivity for certain spectral frequencies of the shock spectrum can be measured with the same uncertainty, using the shock acceleration standard shown in Fig. 8.

The amplitudes of sinusoidal angular accelerations, angular velocities, and rotation angles are measured with a relative measurement uncertainty from $< 0.3\%$ to 0.5% (frequency dependent), using the angular acceleration standard. The complex sensitivity of precise angular accelerometers and angular velocity transducers (reference and transfer standards) can be measured with a measurement uncertainty ranging from $< 0.3\%$ to 0.5% for the magnitude and 0.5° for the phase shift.

The potential high accuracy (low uncertainty) of measurement of laser interferometry can be achieved only in conjunction with high-performance standard exciters, by efficient vibration isolation, and by data acquisition at a high sampling rate, with high resolution and large memory, and by sophisticated data processing procedures. Only small deviations from uniaxial, purely sinusoidal, or defined shock motion are tolerable. Relative motion between the transducer reference surface and the spot(s) sensed by the interferometer must be kept small or negligible. For

detailed descriptions and specifications, see Refs. 13 and 14, as well as www.bipm.org and www.ptb.de.

To suppress the effect of deviations from rectilinear motion in accelerometer calibrations, the displacement is to be measured at four different points equally spaced on the top surface of a back-to-back (BB) accelerometer or on the base surface of a single-ended (SE) accelerometer. In the case of the high-frequency acceleration standard, which simultaneously senses the motion at two different points displaced by 180° (see Fig. 6), two measurement series have been successively carried out, changing the position of the laser light spots by 90° . The phase shift between the sinusoidal vibrations measured at the two positions shifted by 180° has been taken into account when calculating the “mean value” of the motion quantity acting on the transducer to be calibrated. Moreover, the position of mounting of the transducer to be calibrated is changed in angle steps of 90° to compensate the effects of transverse motion if any.

For the calibration of laser vibrometers (see Fig. 7), the effect of relative motion is eliminated by a special adaptor with a reflecting surface and an arrangement that leads the laser light beams from the interferometer of the national measurement standard and the laser vibrometer to be calibrated to the same reflecting point.

5.3 Simultaneous Multicomponent Motion Generation and Measurement

In normal applications, a transducer (e.g., accelerometer) is subjected to motion components in up to 6 degrees of freedom. The triaxial motion exciter is equipped with a measuring table on which the rotational exciter can be mounted. Both exciters can alternatively be used separately. The triaxial motion exciter consists of three electrodynamic vibration exciters that are coupled by a hydrostatic bearing. It can control the vibration parameters on three axes independently. The rotational exciter uses a brushless three-phase hollow-shaft motor that is electronically commutated and servo-controlled and is equipped with an air bearing. The motion quantities can be generated and measured by laser interferometry in the different axes simultaneously and with different user-defined time histories. First calibrations with simultaneous excitation of motion quantities in more than one axis revealed that some transducer designs cause interrelated effects that are not taken into account by the linear superposition principle.⁵² In accelerometer designs using a bending beam, the transverse sensitivity measured without any vibration acting in the main sensitivity axis of the accelerometer may differ considerably from the transverse sensitivity measured in the presence of a vibration acting in the main axis (i.e., when the bending beam is deflected by a vibration to be measured). Triaxial vibration excitation allows, among other things, the transverse sensitivity to be determined with simultaneous excitation of a vibration in the main axis of the transducer, thus simulating application conditions

where the transducer is exposed to multiaxial vibration. The advantage of triaxial excitation for testing the transverse sensitivity of vibration transducers has been taken into account in the revision of ISO 5347-11 (to become ISO 16063-31).⁵³

5.4 Application of National Measurement Standards – Identification of Dynamic Behavior of Transducers

High-quality generation and measurement of motion quantities is required to accurately identify the dynamic characteristics of rectilinear and angular transducers and measuring instruments (reference standards in particular). Some examples are:

- Highest measurement accuracy achieved in accelerometer calibrations so far³⁹
- Comparison results of accurate phase calibrations⁴¹
- Long-term stability of reference accelerometers³⁹
- Calibration of different digital laser vibrometers¹⁴
- Linearity of reference accelerometers (sinusoidal acceleration, dynamic range from 3 m/s² to 200 m/s²)³⁹
- Linearity of reference accelerometers (shock acceleration, dynamic range from 50 m/s² to 100 km/s²)⁴⁷

Figure 9 shows the results of a linearity test of a reference accelerometer, using the PTB techniques

Figure 9 Linearity test of a piezoelectric accelerometer by shock excitation using the shock acceleration standards 5 km/s² and 100 km/s² (see Section 5.2).

and procedures of signal processing in the time domain and in the frequency domain. The sensitivity values obtained for several spectral frequencies of the shock spectrum (frequency domain) revealed that the reference accelerometer behaved linearly within the uncertainty of the investigation of better than 1% up to 50 km/s² at least. The need for such accurate linearity tests is demonstrated in Ref. 54. The shock sensitivity measured by definition in the time domain increases with the acceleration peak value because the shock duration becomes shorter and the shock spectrum shifts to higher frequencies.^{14,47} Above 5 km/s², the shock acceleration standard 100 km/s² was used (standard 6 in Section 5.2); below 5 km/s², the shock acceleration standard 5 km/s² was used (standard 5 in Section 5.2). The leap in the shock sensitivity is caused by different shock durations of these standard devices.

6 EXPRESSION OF UNCERTAINTY IN MEASUREMENTS

6.1 Survey of Procedures of the ISO Guide

Over the last few decades, various concepts and procedures of uncertainty evaluation were proposed and discussed. With the publication of the *ISO Guide to the Expression of Uncertainty in Measurement* (GUM) in 1993, a unified method for the evaluation and expression of measurement uncertainties was accepted worldwide. The accuracy of a measurement is to be described by the expanded uncertainty U for a given coverage factor k or coverage probability P . The purpose of the expanded uncertainty U is to provide an interval $y - U$ to $y + U$ within which the value of Y , the specific quantity subjected to measurement or calibration and estimated by y , can be expected with high probability to lie. The NMIs have made efforts to confidently assert that $y - U \leq Y \leq y + U$. The GUM procedure can briefly be described by the following 6 steps:

Step 1 Establish the model of evaluation:

$$Y = f(X_1, X_2, \dots, X_N) \quad Y, X_i \text{ are random variables}$$

$$y = f(x_1, x_2, \dots, x_N) \quad y, x_i \text{ are estimates of } Y, X_i$$

Step 2 Determine the standard uncertainty $u(x_i)$ of input estimate x_i . Example of rectangular distribution model:

$$u(x_i) = b/\sqrt{3} \quad \text{with} \\ b = (b_+ - b_-)/2 \quad E\{X_i\} = (b_+ + b_-)/2$$

Step 3 Determine the estimated covariance

$$u(x_i, x_j)$$

Step 4 Calculate the uncertainty contributions $u_i(y)$, $u(y_i, y_j)$:

$$u_i(y) = c_i u(x_i) \quad c_i = \left(\frac{\partial f}{\partial X_i} \right)_{x_i}$$

$$u(y_i, y_j) = c_i c_j u(x_i, x_j)$$

Step 5 Calculate the combined uncertainty $u_c(y)$:

$$u_c(y) = \sqrt{\sum_{i=1}^N c_i^2 u^2(x_i) + 2 \sum_{i=1}^{N-1} \sum_{j=i+1}^N c_i c_j u(x_i, x_j)}$$

Step 6 Calculate the expanded uncertainty $U(y)$ from $u_c(y)$:

$$U = k u_c \quad \frac{U}{y} = k \frac{u_c}{y} \quad (k \text{ is coverage factor, preferably } k = 2)$$

6.2 Tools for Uncertainty Evaluations in Vibration Measurements and Calibrations

In vibration and shock measurements and calibrations, the application of the GUM may be difficult and very time consuming unless some possibilities of simplification are used. In Refs. 55 and 56, a survey is given of the problems typically encountered in uncertainty calculations when vibrations are measured or accelerometers calibrated. It is shown how a model function of simple structure can be established for the usually complex relationship between the output quantity (e.g., sensitivity of an accelerometer), the quantity to be measured (e.g., acceleration), and various influence quantities (noise, transverse motion, base strain, etc.). Among other things, nonlinear effects such as the influences of distortion, hum, and noise can be properly taken into account.

A set of rules has been explained that allow the uncertainty components ("standard uncertainties") of the "input quantities X_i " to be estimated in dependence on the degree of information available about the uncertainty sources. Some of the methodical tools described in Refs. 55 and 56 are demonstrated in Annex C of ISO 16063-1⁵⁷ and in the example of Section 6.3. The propagation of the errors and uncertainties within a traceability chain has been described in detail.⁵⁸

6.3 Example: Uncertainty Evaluation of an Accelerometer Calibration

Theoretical and experimental investigations into the errors and uncertainties of measurements of motion quantities ("vibration and shock measurements") at the NMI level have been reported in Refs. 50, 55, 56, and 58. On the basis of the cause-and-effect diagram shown in Fig. 10, detailed uncertainty budgets have been established.⁵⁵ The calibration task reflected by this cause-and-effect diagram is to determine the magnitude S of the complex charge sensitivity of an accelerometer, defined as the ratio of charge amplitude \hat{q} at its output to acceleration amplitude \hat{a} at its input,

$$S = \frac{\hat{q}}{\hat{a}} \quad (1)$$

For the example of interferometric calibration, the relationship

$$S = \frac{1}{(2\pi)^2} \frac{1}{f^2} \frac{\hat{u}}{\hat{s}} \frac{1}{S_A} \prod_i K_i \quad (2)$$

with

$$K_i = (1 - e_i^*) \quad (2a)$$

was derived from Eq. (1), thus expressing the magnitude S of the charge sensitivity of the accelerometer as a function of the measurands voltage amplitude \hat{u} , displacement amplitude \hat{s} , charge amplifier sensitivity (magnitude) S_A , vibration frequency f , and correction factors K_i , which take the relative error components e_i^* into account (for details, see Refs. 55 and 56).

The logical structure of the cause-and-effect diagram of Fig. 10 subdivides the variety of error sources into groups affecting the measurement of voltage, displacement, charge amplifier sensitivity, and frequency. In addition to these four quantities, which are measurands of the indirect measurement of the output quantity S , a fifth path δS is included to take residual (combined) effects into account, which cannot be assigned to any of the four measurands of the indirect measurement.

For the mathematical model Eq. (2) with Eq. (2a) for the measurement of the magnitude of the complex sensitivity of the accelerometer, the expression for the relative combined standard uncertainty

$$\frac{u_c(S)}{S} = \sqrt{\left(\frac{u(\hat{u})}{\hat{u}}\right)^2 + \left(\frac{u(\hat{s})}{\hat{s}}\right)^2 + \left(\frac{2u(f)}{f}\right)^2 + \left(\frac{u(S_q)}{S_q}\right)^2 + \sum_{i=5}^N (u(K_i))^2} \quad (3)$$

can be applied, where $u(x_i)$ is the standard uncertainty of the input estimate x_i , $i = 1, 2, \dots, N$. The expanded uncertainty U is determined by multiplying u_c by a coverage factor k (normally $k = 2$, see Section 6.1, step 6).

The uncertainty evaluation described in detail in Ref. 55 is valid for the sensitivity measurement (magnitude) at a frequency of 800 Hz and an acceleration

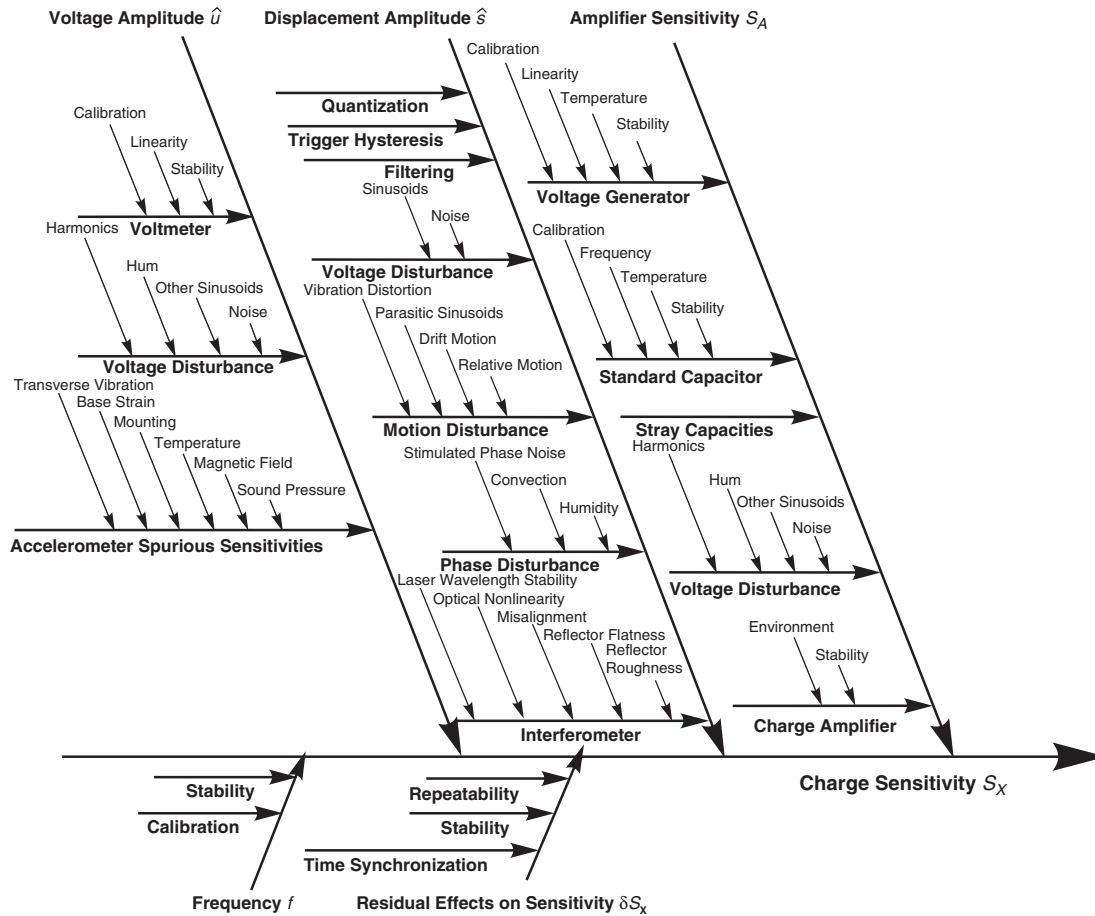

Figure 10 Cause-and-effect diagram for the measurement of the charge sensitivity of an accelerometer (method 1 specified in ISO 16063-11).⁵

amplitude of 50 m/s². The expanded uncertainty U ($k = 2$) of 0.065% resulting from the uncertainty budget⁵⁵ has been rounded to 0.1%, which is the best uncertainty stated by the PTB for vibration measurement and calibrations (e.g., in Ref. 39). The uncertainty evaluations that have been demonstrated for interferometric vibration measurements and primary calibrations of accelerometer standards with expanded uncertainties of $\leq 0.1\%$ for a coverage factor $k = 2$ were assessed by different international comparison measurements (see Ref. 39).

Various further specific uncertainty evaluations carried out for vibration and shock measurements and calibrations based on the GUM⁴ have been published (e.g., Refs. 59 to 63).

PART VI

PRINCIPLES OF NOISE AND VIBRATION CONTROL AND QUIET MACHINERY DESIGN

CHAPTER 54

INTRODUCTION TO PRINCIPLES OF NOISE AND VIBRATION CONTROL

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Machines are used for a variety of purposes. The noise and vibration of appliances is often simply just annoying. The noise and vibration of machines in industry, however, can be intense enough to permanently hurt people. Although each machinery noise and vibration problem is somewhat different, a systematic approach and use of several well-known methods often produce sufficient reduction and acceptable conditions.¹ This chapter begins with a discussion of the source–path–receiver model, continues with a description of the most useful passive noise and vibration control approaches, and concludes with a discussion of the sources of noise and vibration in several important classes of machines and methods of identifying sources. Several individual worked examples are provided of the use of passive noise and vibration control approaches, and a specific example is given of how noise has been reduced on a mobile air compressor.

2 SYSTEMATIC APPROACH TO NOISE PROBLEMS

Noise control should always be incorporated at the design stage wherever possible because there are more low-cost options and possibilities than to make completed machines or installations quieter.^{1–3} After machines are built or installations completed, noise control approaches can still be achieved through various modifications and add-on treatments, but these are frequently more difficult and expensive to implement. Several books deal with the fundamentals of noise control and with practical applications of noise control techniques.^{4–12} Other books deal with acoustics and noise theory.^{13,14}

Noise problems can be described using the simple *source–path–receiver* model⁴ shown in Fig. 1. The *sources* are of two main types: (1) airborne sound sources caused by gas fluctuations (as in the fluctuating release of gas from an engine exhaust) or (2) structure-borne machinery vibration sources that in turn create

Figure 1 Source–path–receiver model for noise problems.

sound fields (e.g., engine surface vibrations). Moreover, these sound pressure and vibration sources are of two types: (1) steady state and (2) impulsive. Both steady-state and impulsive vibrations (caused by impacting parts) are commonly encountered in machines. The *paths* may also be airborne or structure-borne in nature.

Source modifications are the best practice but are sometimes difficult to accomplish. Often changes in the path or at the *receiver* may be the only real options available. The model shown in Fig. 1 is very simple. In reality there will be many sources and paths. The dominant source should be treated first, then the secondary one, and so on. The same procedure can also be applied to the paths. Finally, when all other possibilities are exhausted, the receiver can be treated. If, as in most noise problems, the receiver is the human ear, earplugs or earmuffs or even complete personnel enclosures can be used.

Measurements, calculations, and experience all play a part in determining the dominant noise and vibration sources and paths. The dominant sources (and paths) can sometimes be determined from careful experiments. In some cases, parts of a machine can be turned off or disconnected to help identify sources. In other cases, parts of a machine can be enclosed, and then sequential exposure of machine parts can be used to identify major sources. Frequency analysis of machines can also be used as a guide to the causes of noise, as with the case of the firing frequency in engines, the pumping frequency of pumps and compressors, and the blade-passing frequency of fans. More sophisticated methods are also available involving the use of coherence, cepstrum, and intensity methods. Methods for determining the sources of noise and vibration in machinery are discussed in Chapter 55 of this book.

3 NOISE REDUCTION TECHNIQUES

A study of the literature reveals many successful well-documented methods used to reduce the noise of machines. These can be classified using the source–path–receiver model. Some of the most useful approaches can generally be used only at the source or in the path. Others, such as *enclosure*, can be adapted for use at any location. For instance, a small enclosure can be built inside a machine around a gear or bearing, or a larger enclosure or room can be built around a complete machine. Finally, an enclosure or personnel booth can be built for the use of a machine operator.

Table 1 Passive Noise Control Approaches That May Be Considered for Source, Path, or Receiver

Source	Choose quietest machine source available Reduce force amplitudes Apply forces more slowly Use softer materials for impacting surfaces Balance moving parts Use better lubrication Improve bearing alignment Use dynamic absorbers Change natural frequencies of machine elements Increase damping of machine elements Isolate machine panels from forces Reduce radiating surface areas (by adding holes)
Path	Stagger time of machine operations in a plant Install vibration isolators Use barriers Install enclosures Use absorbing materials Install reactive or dissipative mufflers Use vibration breaks in ductwork Mismatch impedances of materials Use lined ducts and plenum chambers Use flexible ductwork Use damping materials
Receiver	Provide earplugs or earmuffs for personnel Construct personnel enclosures Rotate personnel to reduce exposure time Locate personnel remotely from sources

Table 1 summarizes a large number of approaches that have been found useful in practice.

4 MAIN PASSIVE NOISE CONTROL APPROACHES

In this section the main passive noise control approaches are briefly summarized. These include the use of (1) vibration isolators, (2) acoustical absorbing material, (3) enclosures, (4) barriers, and (5) vibration damping material.

4.1 Use of Vibration Isolators

Vibration isolation has been discussed frequently in the literature. Chapter 59 also presents a detailed review of vibration isolation theory and practice. Vibration isolators are used in two main situations: (1) where a machine source is producing vibration that it is desired to prevent vibration energy flowing to supporting structures and (2) where a delicate piece of equipment (such as an electronics package or precision grinder) must be protected from vibration in the structure. It is the first case that will receive attention here. Primary emphasis is placed on reducing the force transmitted from the machine source to the supporting structure, but a secondary consideration is to reduce the vibration of the machine source itself.

It is often found that machines are attached to metal decks, grills, and sometimes lightweight wood or concrete floors. The machine on its own is usually

incapable of radiating much noise (particularly at low frequency). The supporting decks, grills, and floors, however, tend to act like sounding boards, just as in musical instruments, and amplify the machine noise. Properly designed vibration isolators can overcome this noise problem.

Vibration isolators are of three main types: (1) spring, (2) elastomeric, and (3) pneumatic. Spring isolators are durable but have little damping. Elastomeric isolators are less durable and are subject to degradation due to corrosive environments. They have higher damping and are less expensive. Pneumatic isolators are used where very low frequency excitation is present.

Often the exciting forces are caused by rotational out-of-balance forces in machines or machine elements or by magnetic or friction effects. Usually, these forces are simple harmonic in character. Such forces occur in electric motors, internal combustion engines, bearings, gears, and fans. Sometimes, however, the exciting forces may be impulsive in nature (e.g., in the case of punch presses, stamping operations, guillotines, tumblers, and any machines where impacts occur). The design of vibration isolators for a machine under the excitation of a simple harmonic force is considered below.

Theory of Vibration Isolation A machine may be considered, for simplicity, to be represented by a rigid mass m . If the machine is attached directly to a large rigid massive floor, as shown in Fig. 2, then all the periodic force $F_m(t)$ applied to the mass is directly transmitted to the floor. We will assume that the force on the mass is vertical and $F_m(t) = F_m \sin 2\pi ft$, where F_m is the amplitude of this force, and f is its frequency (Hz).

If a vibration isolator is now placed between the machine and the floor, we can model this system with the well-known single-degree-of-freedom system shown in Fig. 3. The following discussion assumes that the isolators have a constant stiffness and that the damping is viscous in nature.

Suppose, for the moment, that the periodic force is stopped and that the mass m is brought to rest. If the mass m is displaced from its equilibrium position and released, then it will vibrate with a *natural frequency* of vibration f_n given by

$$f_n = \left(\frac{1}{2\pi} \right) \sqrt{\frac{K}{m}} \quad \text{Hz} \quad (1)$$

Figure 2 Rigid machine of mass m attached to a rigid massive floor.

Figure 3 Rigid machine of mass m separated from rigid massive floor by vibration isolator of stiffness K and damping R .

where, in International System (SI) units, K is the stiffness (N/m) and m is the mass (kg). See Chapter 1.

If the exciting force $F_m(t)$ is now resumed, then a force $F_t(t)$ will be transmitted to the rigid floor. This force $F_t(t)$ will be out of phase with $F_m(t)$, but it is simple to show that the ratio of the amplitudes of the forces in the steady state is given by

$$T_F = \frac{F_t}{F_m} = \sqrt{\frac{1 + 4(f/f_n)^2(R/R_c)^2}{[1 - (f/f_n)^2]^2 + 4(f/f_n)^2(R/R_c)^2}} \quad (2)$$

where f is the frequency of the exciting force (Hz), f_n is the natural frequency of vibration of the mass m on the spring (Hz), R is the coefficient of damping (Vs/m), and R_c is the coefficient of critical damping ($R_c = 2\sqrt{mK}$). See Chapter 1 for further discussion on vibration. The ratio F_t/F_m is known as the force transmissibility T_F .

The vibration amplitude A of the machine mass m is given by

$$\frac{A}{F_m/K} = \frac{1}{\{[1 - (f/f_n)^2]^2 + 4(f/f_n)^2(R/R_c)^2\}^{1/2}} \quad (3)$$

The ratio $A/(F_m/K)$ is known as the *dynamic magnification factor* (DMF). This is because F_m/K represents the static displacement of the mass m if a static force of value F_m is applied, while A represents the dynamic displacement amplitude that occurs due to the periodic force of amplitude F_m . Note that the ratio R/R_c is known as the *damping ratio* δ . If $\delta = 1.0$, the damping is called *critical damping*. With most practical vibration isolators, δ may be in the range from about 0.01 to 0.2. Equations (2) and (3) are plotted in Figs. 4 and 5, respectively.

If the machine is run at the natural frequency f_n , we see from Fig. 4 that f/f_n is 1.0 and the force amplitude transmitted to the floor is very large, particularly if the damping in the isolator support is small. If the machine is operated much above the natural frequency, however, then the force amplitude transmitted to the floor will be very small.

Example 1. Machine Isolation Suppose we wish to isolate the 120-Hz vibration of an electric motor. If

we choose isolators so that the system has a natural frequency of 12 Hz, then the ratio $f/f_n = 10$. If the damping in the isolator system is $R/R_c = 0.1$, the force transmissibility will be only about 0.025, or 2.5%.

We define the efficiency η of the isolator as

$$\eta = (1 - T_F) \times 100\% \quad (4)$$

Thus in Example 1 the isolator efficiency is 97.5%.

To reduce the force transmissibility still further, we could use softer isolators and choose a still lower resonance frequency. There is some danger in doing this, however, because the static deflection of the machine will naturally increase if we use softer isolators. Since a large static deflection may be undesirable (it may interfere with the operation of the machine), this restricts the softness of the isolator and thus how low we can make the natural frequency f_n . The static deflection d produced in the isolator by the gravity force on the mass m is given by $d = mg/K$. We have already seen that the natural frequency is related to K and m by $f_n = (1/2\pi)\sqrt{K/m}$. Hence we can relate the static deflection d to the natural frequency f_n :

$$d = \frac{g}{4\pi^2 f_n^2} \quad (5)$$

where the static deflection d is given in centimetres (or inches) and g is the acceleration of gravity, 981 cm/s².

The relationship given in Eq. (5) has been plotted in Fig. 6. The greatest static deflection d that can be allowed from operational considerations should be chosen. This will then allow a determination of the lowest allowable f_n . It should be noted that excessive static deflection may interfere with the operation of the machine by causing alignment problems. Also, using isolators with a small vertical stiffness usually means that they may have a small horizontal stiffness, and there will be stability problems. Both these considerations limit the lowest allowable f_n .

Simple Design Procedure and Worked Example

With springs, the damping is small (usually $\delta < 0.1$), and we may use Eqs. (2) and (3) and Figs. 4 and

Figure 4 Force transmissibility T_F for the rigid machine–isolator–rigid floor system.

5, assuming that $\delta = 0$. With $\delta = 0$ (or, equivalently, $R = 0$), Eqs. (2) and (5) give

$$T_F = \frac{F_t}{F_m} = \frac{1}{1 - 4\pi^2 f^2 d/g} \quad (6)$$

This result is plotted in Fig. 7. The suggested procedure is as follows.

1. Establish the total weight of the machine and the lowest forcing frequency experienced.
2. From Fig. 7 select the force transmissibility allowable (this determines the static deflection, given the lowest forcing frequency).
3. From the spring constants given by the manufacturer, the machine weight, and the static

deflection, choose the appropriate vibration isolator.

Example 2. Machine Isolation An electric motor of mass 100 kg and a reciprocating compressor of mass 500 kg are mounted on a common support. The motor runs at 2400 revolutions/minute (rpm) and by a belt drives the compressor at 3000 rpm. The vertical force fed to the support is thought to be excessive. Choose six equal spring mounts to provide a force transmissibility not exceeding 5%.

1. The total machine weight is 600 kg, and the lowest forcing frequency is 2400 rpm (or 40 Hz).
2. From Fig. 7, the static deflection required is 0.33 cm (0.13 in).

Figure 5 Dynamic magnification factor (DMF) for the rigid machine-isolator-floor system.

3. Thus, since there are six spring isolators, each must support a mass of 100 kg. This requires a spring constant for each isolator of $981/0.33 = 3000 \text{ N/cm}$.

As a check on the calculation, we see from Fig. 6 that a static deflection of 0.33 cm. requires a natural frequency of about 8.6 Hz. Thus, the ratio of forcing frequency to natural frequency $f/f_n = 40/8.6 = 4.65$. From Fig. 4, with zero damping, $T_F = 0.05$, which agrees with the design requirement.

Machine Vibration There are several other factors that should be considered in isolator design. First,

Figure 6 Relationship between natural frequency f_n of machine-isolator-floor system and static deflection d of machine.

Figure 7 Relationship (for a linear isolator) between forcing frequency f , force transmissibility T_F , and static deflection d of machine-isolator-floor system, without damping ($R = 0$). (Note deflection given in inches. 1 inch = 2.54 cm.)

we notice from Figs. 4 and 5 that when a machine is started or stopped, it will run through the resonance condition and then, momentarily, $f/f_n = 1$. When passing through the resonance condition, large vibration amplitudes can exist on the machine, and the force transmitted will be large, particularly if the damping is small. Assuming viscous damping, to provide small force transmissibility at the operating speed, small damping is required; however, to prevent excessive machine vibration and force transmission during stopping and starting, large damping is needed. These two requirements are conflicting. Fortunately, some forces, such as out-of-balance forces, are much reduced during starting and stopping. However, it is normal to provide a reasonable amount of damping ($\delta = 0.1$ to 0.2) in spring systems to reduce these starting and stopping problems. The severity of the machine vibration problem can be gauged from Fig. 8.

Use of Inertia Blocks Inertia blocks are normally made from concrete poured onto a steel frame. If the mass supported by the vibration isolators is increased by mounting a machine on an inertia block, the static deflection will be increased. If the isolator stiffness is correspondingly increased to keep the static deflection the same, then there is no change in the resonance

Figure 8 Machine vibration severity chart showing peak-to-peak vibration (2A) mils (1 mil = 0.001 in. = 0.0254 mm).

frequency or the force transmissibility T_F . The use of an inertia block does, however, result in a reduced vibration amplitude of the machine mass. It also has additional advantages including (1) *improving stability* by providing vibration isolator support points that are farther apart, (2) *lowering the center of gravity* of the system, thus improving stability and reducing the effect of coupled modes and rocking natural frequencies, (3) producing more even weight distribution for machines often enabling the use of symmetrical vibration isolation mounts, (4) *functioning as a local acoustical barrier* to shield the floor of an equipment room from the noise radiated from the bottom of the machine and reducing its transmission to rooms below, and (5) *reducing the effect on the machine of external forces* such as transient loads or torques caused by operation of motors or fans or rapid changes in machine load or speed.

Other Considerations The performance of vibration isolators in the high-frequency range ($f/f_n \geq 1$) is often disappointing. There are several possible reasons, but often they all result in an increase in force transmissibility T_F for $f/f_n \geq 1$. Usually, the reasons are deviations from the simple single-degree-of-freedom model as mentioned below.⁵

(a) Support Flexibility If the assumption that the support is rigid does not hold, then the support will also deflect (e.g., a flexible floor). If the isolator stiffness is similar in magnitude to that of the supporting floor, then additional resonances in the floor-machine system will occur for $f/f_n > 1$. It is normal practice to choose isolators (assuming a rigid support or floor) to have a natural frequency well below the fundamental natural frequency of the floor itself. (If possible there should not be any machine-exciting frequencies in the frequency range 0.8 to 1.3 times the floor fundamental natural frequency.) The fundamental natural frequency of a wood floor is usually in the 20 to 30-Hz frequency range, while that of a concrete floor is in the 30–100-Hz range.

(b) Machine Resonances Internal resonances in the machine structure will also increase the force transmissibility T_F in a similar manner to support

flexibility. Increasing the stiffness and/or the damping of machine members can help to reduce this effect.

(c) Standing-Wave Effects Standing-wave effects in the vibration isolators can significantly decrease their performance and increase force transmissibility for $f/f_n \geq 1$, but this typically occurs only at high frequency. This effect can be reduced by increasing the damping in the isolators. Springs particularly suffer from this problem because of their low inherent damping. Soft materials (such as felt or rubber) placed between the spring and the support can alleviate the problem. In elastometric isolators the effects of standing wave resonators are small because of their higher damping.

(d) Shock Isolation If the forces in the machine are impulsive in character (such as caused by repeated impacts), then the discussion for isolation of the single-degree-of-freedom model presented so far can still be used. It is normal practice to choose an isolator that provides a natural period T ($T = 1/f_n$), which is much greater than the shock pulse duration but less than the period of repetition of the force.

Example 3. Shock Isolation A nail-making machine cuts nails five times each second ($T = 0.2$ s). The shock pulse duration is approximately 0.015 s. What is a suitable choice of vibration isolator for the machine? Elastometric isolators that provide a natural period of vibration of 0.1 s (natural frequency of 10 Hz) would be a good choice. They have high damping.

4.2 Use of Sound-Absorbing Materials

Sound-absorbing materials have been found to be very useful in the control of noise. They are used in a variety of locations: close to sources of noise (e.g., close to sources in electric motors), in various paths, (e.g., above barriers or inside machine enclosures), and sometimes close to a receiver (e.g., inside earmuffs). When a machine is operated inside a building, the machine operator usually receives most sound through a direct path, while people situated at greater distances receive sound mostly through reflections (see Fig. 9).

Figure 9 Paths of direct and reflected sound emitted by a machine in a building.

The relative contributions of the sound reaching people at a distance through direct and reflected paths are determined by how well the sound is reflected and absorbed by the walls in the building. The *absorption coefficient* of a material $\alpha(f)$, which is a function of frequency, has already been defined in Chapter 2:

$$\alpha(f) = \frac{\text{sound intensity absorbed}}{\text{sound intensity incident}} \quad (7)$$

Thus $\alpha(f)$ is the fraction of incident sound intensity that is absorbed, and it can vary between 0 and 1. Materials that have a high value of α are usually fibrous or porous. Fibrous materials include those made from natural or artificial fibers including glass fibers. Porous materials made from open-celled polyurethane foams are also widely used. The properties and use of sound-absorbing materials are discussed in more detail in Chapter 57.

It is believed that there are two main mechanisms by which the sound is absorbed in materials: (1) viscous dissipation of energy by the sound waves as they propagate in the narrow channels of the material and (2) energy losses caused by friction as the fibers of the material rub together under the influence of the sound waves. These mechanisms are illustrated in Fig. 10. In both mechanisms sound energy is converted into heat. The sound absorption coefficient of most acoustical materials increases with frequency (see Fig. 11), and coefficients of some common sound-absorbing materials and construction materials are shown in Tables 2 and 3. The noise reduction coefficient (NRC) of a sound-absorbing material is defined as the average of the absorption coefficients at 250, 500, 1000, and 2000 Hz (rounded off to the nearest multiple of 0.05).

Figure 10 The two main mechanisms believed to exist in sound-absorbing materials: (a) viscous losses in air channels and (b) mechanical friction caused by fibers rubbing together.

In the case of machinery used in reverberant spaces, the reduction in sound pressure level L_p in the reverberant field caused by the addition of sound-absorbing material placed on the walls or under the roof (see Fig. 12) can be estimated for a source of sound power level L_w from the so-called room equation:

$$L_p = L_w + 10 \log \left(\frac{D}{4\pi r^2} + \frac{4}{R} \right) \quad (8)$$

where R is the *room constant* and is given by $R = S\bar{\alpha}/(1 - \bar{\alpha})$, $\bar{\alpha}$ is the surface average absorption

Table 2 Typical Sound Absorption Coefficients $\alpha(f)$ of Common Acoustical Materials

Materials	Frequency (Hz)

**Figure 11** Sound absorption coefficient α and noise reduction coefficient (NRC) for typical fiberglass form-board of different thicknesses.

coefficient of the walls, D is the source directivity (see Chapter 1), and r is the distance in metres from the source. The surface average absorption coefficient $\bar{\alpha}$ may be estimated from

$$\bar{\alpha} = \frac{S_1\alpha_1 + S_2\alpha_2 + S_3\alpha_3 + \dots}{S_1 + S_2 + S_3 + \dots} \quad (9)$$

where S_1, S_2, S_3, \dots are the surface areas of material with absorption coefficients $\alpha_1, \alpha_2, \alpha_3, \dots$. For the suspended absorbing panels shown in Fig. 12, both sides of the panel are normally included in the surface area calculation.

If the sound absorption is increased, then from Eq. (8) the change in sound pressure level ΔL in the reverberant space (beyond the critical distance r_c) (see Chapter 1) is

$$\Delta L = L_{p1} - L_{p2} = 10 \log \frac{R_2}{R_1} \quad (10)$$

**Figure 12** Sound-absorbing material placed on the walls and under the roof and suspended as panels in a factory building.

If $\bar{\alpha} \ll 1$, then the reduction in sound pressure level (sometimes called the *noise reduction*) is given by

$$\Delta L \approx 10 \log \frac{S_2 \bar{\alpha}_2}{S_1 \bar{\alpha}_1} \quad (11)$$

where S_2 is the total surface area of the room walls, floor, and ceiling and any suspended sound-absorbing material, $\bar{\alpha}_2$ is the average sound absorption coefficient of these surfaces after the addition of sound-absorbing material, and S_1 and $\bar{\alpha}_1$ are the area and the average sound absorption coefficient before the addition of the material. The terms $S\bar{\alpha}$ are known as absorption areas.

Example 4. Reverberant Noise Reduction Using Absorbing Materials. A machine source operates in a building of dimensions 30 m \times 30 m with a height of 10 m. Suppose the average absorption coefficient is $\bar{\alpha} = 0.02$ at 1000 Hz. What would be the noise reduction in the reverberant field if 100 sound-absorbing panels with dimensions 1 m \times 2 m each with an absorption coefficient of $\bar{\alpha} = 0.8$ at 1000 Hz were suspended from the ceiling (assume both sides absorb sound)? The room surface area = $2(900) + 4(300) = 3000 \text{ m}^2$; therefore $R_1 = (3000 \times 0.02)/0.98 = 60/0.98 = 61.2$ sabins (m^2). The new average absorption coefficient $\bar{\alpha}_2 = (3000 \times 0.02 + 200 \times 2 \times 0.8)/3400 = 60 + 320 = 380/3400 = 0.11$. The new room constant is $(3400 \times 0.11)/0.89 = 420$ sabins (m^2). Thus from Eq. (10) the predicted noise reduction $\Delta L = 10 \log(420/61.2) = 8.3 \text{ dB}$. This calculation may be repeated at each frequency for which absorption coefficient data are available. It is normal to assume that about 10 dB is the practical limit for the noise reduction that can be achieved by adding sound-absorbing material in industrial situations.

4.3 Acoustical Enclosures

Acoustical enclosures are used wherever containment or encapsulation of the source or receiver are a good, cost-effective, feasible solution. They can be classified in four main types: (1) large loose-fitting or room-size enclosures in which complete machines or personnel are contained, (2) small enclosures used to enclose small machines or parts of large machines, (3) close-fitting enclosures that follow the contours of a machine or a part, and (4) wrapping or lagging materials often used to wrap pipes, ducts, or other systems.

The performance of such enclosures can be defined in three main ways⁵: (1) *noise reduction* (NR), the difference in sound pressure levels between the inside and outside of the enclosure, (2) *transmission loss* (TL, or equivalently the *sound reduction index*), the difference between the incident and transmitted sound intensity levels for the enclosure wall, and (3) *insertion loss* (IL), the difference in sound pressure levels at the receiver point *without* and *with* the enclosure wall in place. The definitions for the NR, TL, and IL performance of an enclosure are similar to those for mufflers (Chapters 83 and 85) and barriers (Chapters 58 and 122). Enclosures can either be complete

or partial (in which some walls are removed for convenience or accessibility). Penetrations are also often necessary to provide access or cooling.

The transmission coefficient τ of a wall may be defined as

$$\tau = \frac{\text{sound intensity transmitted by wall}}{\text{sound intensity incident on wall}} \quad (12)$$

and this is related to the TL (or sound reduction index) by

$$\text{TL} = 10 \log \frac{1}{\tau} \quad (13)$$

If the sound fields can be considered to be reverberant on the two sides of a complete enclosure, then

$$\text{NR} = L_{p1} - L_{p2} = \text{TL} + 10 \log \frac{A_2}{S_e} \quad (14)$$

where L_{p1} and L_{p2} are the sound pressure levels on the transmission and receiving sides of the enclosure. $A_2 = S_2 \bar{\alpha}_2$ is the absorption area in square metres or feet in the receiving space material where $\bar{\alpha}_2$ is the average absorption coefficient of the absorption material in the receiving space averaged over the area S_2 , and S_e is the enclosure surface area in square metres or feet.

Equation (14) can be used to determine the TL of a partition of surface area S_e placed between two isolated reverberation rooms in which a noise source creates L_{p1} in the source room, and this results in L_{p2} in the receiving room. Also Eq. (14) can be used to design a personnel enclosure. If the enclosure is located in a factory building in which the reverberant level is L_{p1} , then the enclosure wall TL and interior absorption area A_2 can be chosen to achieve an acceptable value for the interior sound pressure level L_{p2} . In the case that the surface area S_2 of the interior absorbing material $S_2 = S_e$, the enclosure surface area, then Eq. (14) simplifies to

$$\text{NR} = \text{TL} + 10 \log \bar{\alpha}_2 \quad (15)$$

We see that normally the NR achieved is less than the TL. Also when $\bar{\alpha}_2$, the average absorption coefficient of the absorbing material in the receiving space, approaches 1, then $\text{NR} \rightarrow \text{TL}$ (the expected result), although when $\bar{\alpha}_2 \rightarrow 0$, then the theory fails.

Example 5. Personnel Enclosure If the reverberant level in a factory space is 90 dB in the 1000-Hz one-third octave band, what values of TL and $\bar{\alpha}$ should be chosen to ensure that the interior level inside a personnel enclosure is below 60 dB? Assuming that $S_2 = S_e$, then if TL is chosen as 40 dB and $\bar{\alpha} = 0.1$, $\text{NR} = 40 + 10 \log 0.1 = 40 - 10 = 30 \text{ dB}$, and $L_{p2} = 60 \text{ dB}$. If $\bar{\alpha}$ is increased to 0.2, then $\text{NR} = 40 + 10 \log 0.2 = 40 - 7 = 33$ and $L_{p2} = 57 \text{ dB}$, meeting the requirement. Note that in general, since TL varies

with frequency [see Eq. (18)], then this calculation would have to be repeated for each one-third octave band center frequency of interest. At low frequency, since large values of TL and $\bar{\alpha}$ are difficult to achieve, it may not be easy to obtain large values of NR.

When an enclosure is used to contain a source, it works by reflecting the sound field back toward the source causing an increase in the sound pressure level inside the enclosure. From energy considerations the insertion loss would be zero if there were no acoustical absorption inside. The buildup of sound energy inside the enclosure, however, can be reduced significantly by the placement of sound-absorbing material inside the enclosure. It is also useful to place sound-absorbing materials inside personnel protective booths for similar reasons. In general, it is difficult to predict the insertion loss of an enclosure. For one installed around a source with a considerable amount of absorbing material used inside to prevent *any* interior reverberant sound energy buildup, then from energy considerations:

$$IL \approx TL$$

if the receiving space is quite absorbent and if IL and TL are wide-frequency-band averages (e.g., at least one octave). If insufficient absorbing material is placed inside the enclosure, the sound pressure level will build up inside the enclosure by multiple reflections, and the enclosure effectiveness will be degraded. From energy considerations it is obvious that if there is no sound absorption inside ($\bar{\alpha} = 0$), the enclosure will be useless, and its IL will be zero.

An estimate of the insertion loss of intermediate cases $0 < \bar{\alpha} < 1$ can be obtained by assuming that the sound field inside the enclosure is reverberant and that the interior surface of the enclosure is lined with absorbing material of average absorption coefficient $\bar{\alpha}$. With the assumptions that (1) the average absorption coefficient in the room containing the noise source is not greater than 0.3 (which is true for most reverberant factory or office spaces), (2) the noise source does not provide direct mechanical excitation to the enclosure, and (3) the noise source occupies less than about 0.3 to 0.4 of the enclosure volume, then it may be shown that the insertion loss of a loose-fitting enclosure made to contain a noise source situated in a reverberant room is⁶

$$IL = L_{p1} - L_{p2} = TL + 10 \log \frac{A_e}{S_e} \quad (16)$$

where L_{p1} is the reverberant level in the room containing the noise source (without the enclosure), L_{p2} is the reverberant level at the same point (with the enclosure), A_e is the absorption area inside the enclosure $S_i \bar{\alpha}_i$, and $\bar{\alpha}_i$ is the surface average absorption coefficient of this material. In the case that the surface area of the enclosure $S_e = S_i$, the area of the interior absorbing material, then Eq. (16) simplifies to

$$IL = TL + 10 \log \bar{\alpha}_i \quad (17)$$

It is observed that, in general, the insertion loss of an enclosure containing a source is less than the transmission loss. Also when $\bar{\alpha}_i$ the average absorption coefficient of the internal absorbing material approaches 1, then $IL \rightarrow TL$ (the expected result), although when $\bar{\alpha}_i \rightarrow 0$, then this theory fails.

Example 6. Machine Enclosure If the sound pressure level L_{p1} in a reverberant factory space caused by a machine source in the 1000-Hz one-third octave band is 85 dB, what values of TL and $\bar{\alpha}$ should be chosen to ensure that the reverberant level is reduced to be below 60 dB? Assuming that $S_i = S_e$, then if TL is chosen to be 30 dB and $\bar{\alpha} = 0.1$, $IL = 30 + 10 \log 0.1 = 30 - 10 = 20$ dB and $L_{p2} = 65$ dB. If $\bar{\alpha}$ is increased to 0.2, then $IL = 30 + 10 \log 0.2 = 30 - 7 = 23$ dB and $L_{p2} = 62$ dB. If $\bar{\alpha}$ is increased to 0.4, then $IL = 30 + 10 \log 0.4 = 30 - 4 = 26$ dB and $L_{p2} = 59$ dB, thus meeting the requirement. As in Example 5, we note that since TL varies with frequency f [see Eq. (18)], this calculation should be repeated at each frequency of interest. At low frequency, since large values of TL and $\bar{\alpha}$ are hard to obtain, it may be difficult to obtain large values of IL.

Thus the transmission loss can be used as a rough guide to the IL of a sealed enclosure, only if allowance is made for the sound absorption inside the enclosure. The transmission loss of an enclosure is normally dominated by the mass/unit area m of the enclosure walls (except in the coincidence-frequency region). This is because the stiffness and damping of the enclosure walls are unimportant, the response is dominated by inertia $m(2\pi f)$, where f is the frequency in hertz. The transmission loss of an enclosure wall for sound arriving from all angles is approximately

$$TL = 20 \log(mf) - C \quad \text{dB} \quad (18)$$

where m is the surface density (mass/unit area) of the enclosure walls and $C = 47$ if the units of m are kg/m^2 and $C = 34$ if the units are lb/ft^2 . Figure 13 shows that the transmission loss of a wall [given by Eq. (18)] theoretically increases by 6 dB for doubling of frequency or for doubling of the mass/unit area of the wall. If some areas of the enclosure walls have a significantly poorer TL than the rest; then this results in a degradation in the overall transmission loss of the enclosure. Where the enclosure surface is made of different materials (e.g., wood walls and window glass), then the average transmission loss TL_{ave} of the composite wall is given by

$$TL_{\text{ave}} = 10 \log 1/\bar{\tau} \quad (19)$$

where the average transmission coefficient $\bar{\tau}$ is

$$\bar{\tau} = \frac{S_1 \tau_1 + S_2 \tau_2 + \cdots + S_n \tau_n}{S_1 + S_2 + S_3 + \cdots + S_n} \quad (20)$$

where τ_i is transmission coefficient of the i th wall element and S_i is the surface area of i th wall element

Figure 13 Variation of mass law transmission loss (TL) of a single panel [see Eq. (18)].

Figure 14 Transmission loss of enclosure walls with holes as a function of transmission loss (TL) of enclosure wall without holes and percentage open area of holes

(m^2). If holes or leaks occur in the enclosure walls and if the TL of the holes is assumed to be 0 dB, then Fig. 14 shows the degradation in the average TL of the enclosure walls. If the penetrations in the enclosure walls are lined with absorbing materials, as shown in

Fig. 15, then the degradation in the enclosure TL is much less significant.

Case History: Enclosure for a Mobile Compressor Figure 16 shows an enclosure for a compressor driven by a diesel engine. In this design,

Figure 15 Enclosures with penetrations (for cooling) lined with sound absorbing materials: (a) lined ducts and (b) lined baffles with double-door access provided to interior of machine.

Figure 16 Major components and cooling airflow of an air compressor.¹⁵

Figure 17 Experimental setup.¹⁵

sound-absorbing material is located inside the enclosure, and air paths are provided for the passage of cooling air. Reference 15 gives extensive details of a theoretical and experimental acoustical design study of the inlet cooling duct for the compressor enclosure. In this study, noise control approaches such as those shown in Fig. 15 had already been undertaken by the manufacturer. In the production unit, a baffle (a small crosswise barrier) was installed to reduce the noise of the cooling fan radiated out of the cooling air inlet. It was desired to reduce the overall noise of the compressor unit in production. An experimental test setup was built as shown in Fig. 17. The experiments showed that the insertion loss produced by the air inlet baffle could be increased only slightly with changes of baffle location; however, a significant insertion loss at frequencies above 500 Hz was achieved by lining the cooling air duct with sound-absorbing material. The sound absorbing material that was most effective was found to be 25.4-mm-thick fiberglass covered with

23% porosity metal sheet. The fiberglass had a density of 48 kg/m^3 . Figure 18 shows the insertion loss measured on the test setup presented in Fig. 17: (1) with the polyurethane foam as installed in the original production unit and (2) with the 25.4-mm-thick 48-kg/m^3 fiberglass and perforated metal facing as the absorption material inlet duct lining used later in this study.

It was decided to make only two main improvements to the compressor unit to reduce its noise: (1) increasing the sound absorption coefficient of the cooling air duct lining and (2) replacing the silencer (muffler) on the engine/compressor air intake with one having a higher value of insertion loss. Figure 19 shows the effect of these two changes on the sound power level of the compressor unit.¹⁵

Other Industrial Enclosures Figure 20 shows an enclosure built for a band saw. A sliding window is provided that can be opened for access to controls. A sliding door is also provided that can be closed as much as possible around items fed to the band saw.

Figure 18 Inlet duct insertion loss measured on the test setup with: —, polyurethane foam installed in production; - - -, fiberglass and perforated metal used as absorption material.¹⁵

Figure 19 A-weighted sound power level of the air compressor before and after modifications: —, before modification and - - - after modification.¹⁵

The interior of the enclosure is lagged with 50 mm of sound-absorbing material. Enclosures are available from manufacturers in a wide variety of ready-made modular panels (see Fig. 21). Figure 21 shows how these panels can be built into a variety of complete machine enclosures and partial and complete personnel enclosures.

Close-Fitting Enclosures If the noise source occupies no more than about one-third of the volume of a sealed enclosure, then the simple theory described by Eqs. (16) and (17) can be used. However, in many cases when machines are enclosed, it is necessary to locate the enclosure walls close to the machine surfaces, so that the resulting air gap is small. Such enclosures are termed *close-fitting enclosures*. In such cases the sound field inside the enclosure is not reverberant or diffuse and the theory discussed so far can be used only for a first approximation of the insertion loss of an enclosure. There are several effects that occur with close-fitting enclosures.

First, if the source is not a constant velocity source then in principle the close-fitting enclosure can “load” it so that it produces less sound power. However, in most machinery noise problems, the source behaves like a constant velocity source and the loading effect is negligible. Second, and more importantly, are the reductions in the insertion loss that occur at certain frequencies (when the enclosure becomes “transparent”). See the frequencies f_0 and f_{sw} in Fig. 22. When an enclosure is close-fitting, then to a first approximation the sound waves approach the enclosure walls at normal incidence instead of random incidence. When the air gap is small, then a resonant condition at frequency f_0 occurs where the enclosure wall mass is opposed by the wall and air gap stiffness. In addition standing-wave resonances can occur in the air gap at frequencies f_{sw} . These resonances can be reduced by the placement of sound-absorbing material in the air gap.^{16,17} Jackson has produced simple theoretical models for close-fitting enclosures that assume a uniform air gap.^{16,17} However, in practice,

Figure 23 Sound waves reflected and diffracted by barrier and acoustical shadow zone.

the air gap varies with real enclosures, and these simple theoretical models and some later ones can only be used to give some guidance of the insertion loss to be expected in practice. Finite element and boundary element approaches can be used to make insertion loss predictions for close-fitting enclosures with complicated geometries.

4.4. Barriers

An obstacle placed between a noise source and a receiver is termed a *barrier* or *screen*, as explained in Chapter 58. When a sound wave approaches the barrier, some of the sound wave is reflected and some is transmitted past (see Fig. 23). At high frequency, barriers are quite effective, and a strong acoustical “shadow” is cast. At low frequency (when the wavelength can equal or exceed the barrier height), the barrier is less effective, and some sound is diffracted into the shadow zone. Indoors, barriers are usually partial walls. Outdoors, the use of walls, earth berms, and even buildings can protect residential

Figure 24 Attenuation of a barrier as a function of Fresnel number N for point and incoherent line sources.

areas from traffic and industrial noise sources. (see Chapter 122.) Empirical charts are available to predict the attenuation of a barrier.⁴ Figure 24 shows the *insertion loss* or reduction in sound pressure level expected after installation of a semiinfinite barrier in free space between a source and receiver. If barriers are used inside buildings, their performance is often disappointing because sound can propagate into the shadow zone by multiple reflections. To produce acceptable attenuation, it is important to suppress these reflections by the use of sound-absorbing material, particularly on ceilings just above the barrier. In Fig. 24, N is the dimensionless Fresnel number related to the shortest distance over the barrier $d_1 + d_2$ and the straight line distance d between the source S and receiver R :

$$N = 2(d_1 + d_2 - d)/\lambda \quad (21)$$

where λ is the wavelength and d_1 and d_2 are shown in Fig. 24.

4.5 Damping Materials

Load-bearing and non-load-bearing structures of a machine (panels) are excited into motion by mechanical machine forces resulting in radiated noise. Also, the sound field inside an enclosure excites its walls into vibration. When resonant motion dominates the vibration, the use of damping materials can result in

Figure 25 Different ways of using vibration damping materials: (a) free layer, (b) multiple constrained layer, (c) multilayer tile spaced treatment, (d) sandwich panel, (e) tuned damper, and (f) resonant beam damper. Shaded elements represent viscoelastic material.

significant noise reduction. In the case of machinery enclosures, the motion of the enclosure walls is normally mass controlled (except in the coincidence-frequency region), and the use of damping materials is often disappointing. Damping materials are often effectively employed in machinery in which there are impacting parts since these impacts excite resonant motion.

Damping involves the conversion of mechanical energy into heat. Damping mechanisms include friction (rubbing) of parts, air pumping at joints, sound radiation, viscous effects, eddy currents, and magnetic and mechanical hysteresis. Rubbery, plastic, and tarry materials usually possess high damping. During compression, expansion, or shear, these materials store elastic energy, but some of it is converted into heat as well. The damping properties of such materials are temperature dependent. Damping materials can be applied to structures in a variety of ways. Figure 25 shows some common ways of applying damping materials and systems to structures. Chapter 60 describes damping mechanisms in

more detail and how damping materials can be used to reduce vibration in some practical situations.

CHAPTER 55

NOISE AND VIBRATION SOURCE IDENTIFICATION

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

In most machinery noise and vibration control problems, knowledge of the dominant noise and vibration sources in order of importance is very desirable, so that suitable modifications can be made. In a complicated machine, such information is often difficult to obtain, and many noise and vibration reduction attempts are made based on inadequate data so that frequently expensive or inefficient noise and vibration reduction methods are employed. Machine noise and vibration can also be used to diagnose increased wear. The methods used to identify noise and vibration sources will depend on the particular problem and the time and resources (personnel, instrumentation, and money) and expertise available and on the accuracy required. In most noise and vibration source identification problems, it is usually the best practice to use more than one method to ensure greater confidence in the identification procedure. Well-tried methods are available and novel methods are under development.

2 SOURCE-PATH-RECEIVER

Noise and vibration source and path identification methods of differing sophistication have been in use for many years.^{1–29} Some approaches are used in parallel with others to provide more information about sources and increased confidence in the results. In recent years, a considerable amount of effort has been devoted in the automobile industry to devise better methods of noise and vibration source and path identification.^{30–51} Most effort has been expended on interior cabin noise and separating airborne^{30–35} and structure-borne^{36–39} paths. Engine and power train noise and vibration sources and paths^{40–45} and tire noise^{46,47} have also received attention. This effort has been expended not only to make the vehicles quieter but to give them a distinctive manufacturer brand sound. See Chapter 67. More recently these methods have been extended and adapted in a variety of ways to produce improved methods for source and path identification.^{54–75} One example is the so-called transfer path analysis (TPA) approach⁶⁹ and variations of it, which to some extent are based on an elaborated version of the earlier coherence approach for source and path modeling.^{21–29} See Sections 7 and 9 of this chapter. Commercial softwares are now available using the TPA and other related approaches for noise and vibration source and path identification. Pass-by exterior noise sources of automobiles and railroad vehicles has also been studied.^{48–53}

Figure 1 Sources and paths of airborne and structure-borne noise and vibration resulting in interior noise in an airplane cabin.

As discussed in Chapter 54, noise and vibration energy must flow from a *source* through one or more *paths* to a *receiver* (usually the human ear). Figure 1 in Chapter 54 shows the simplest model of a *source–path–receiver* system. Noise sources may be *mechanical* in nature (caused by impacts, out-of-balance forces in machines, vibration of structural parts) or *aerodynamic* in nature (caused by pulsating flows, flow–structure interactions, jet noise, turbulence). Noise and vibration energy can flow through a variety of airborne and structure-borne paths to the receiver. Figure 1 shows an example of a propeller-driven airplane. This airplane situation can be idealized as the much more complicated source–path–receiver system shown in Fig. 2. In some cases the distinction between the source(s) and path(s) is not completely clear, and it is not easy to neatly separate the sources from the paths. In such cases, the sources and paths must be considered in conjunction. However, despite some obvious complications, the source–path–receiver model is a useful concept that is widely used. In this chapter we will mainly concern ourselves with machinery noise sources. We note that *cutting* or *blocking* one or more noise and/or vibration *paths* often gives invaluable information about the noise sources.

3 CLUES TO NOISE SOURCES

There are various characteristics of a sound field that give indications of the types of noise sources

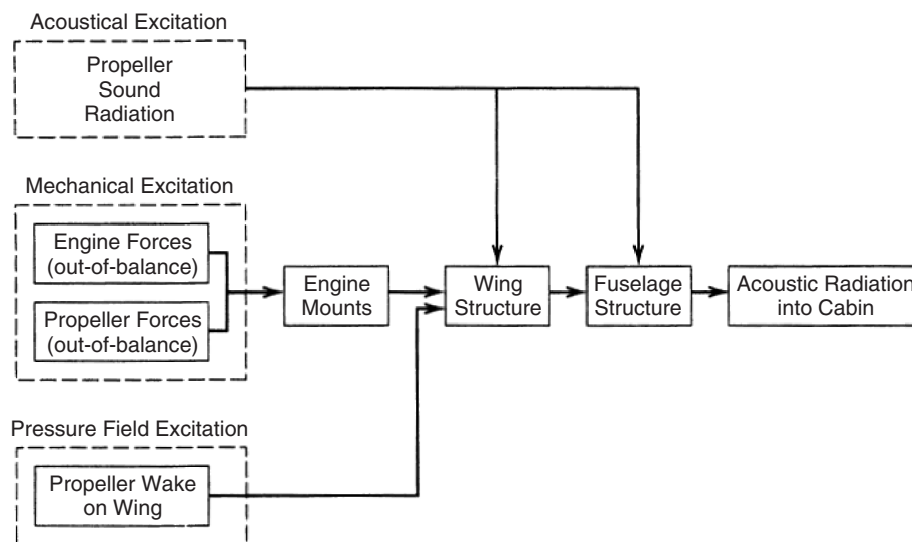

Figure 2 Source-path-receiver system showing airborne and structure-borne paths for a twin-engine propeller-driven airplane.

present and their spatial distribution. These include the frequency distribution of the sound pressure level, the directional properties of the sound field, and the variation of the sound pressure level with distance from the sources. Knowledge of the variation in the sound pressure level with time can also be instructive. For more sophisticated measurements it is useful to have some theoretical understanding of the propagation of sound from idealized sound source models—monopole, dipole, quadrupole, line source, piston—and the generation of sound caused by mechanical systems—mechanical impacts and vibrating beam and plates. See Chapters 1, 2, 3, and 6. Such theoretical understanding not only guides us in deciding which measurements to make but also aids in interpreting the results. In fact as the measurements made become more sophisticated, increasing care must be taken in their interpretation. There is a danger with sophisticated measurements of collecting large amounts of data and then either being unable to interpret them or reaching incorrect conclusions. With the advent of increasingly sophisticated signal processing equipment and software, knowledge of signal analysis and signal processing theory has become very important. See Chapters 40 and 42.

4 CLASSICAL METHODS OF IDENTIFYING NOISE AND VIBRATION SOURCES

Some of the elementary or classical methods of identifying noise sources have been reviewed in detail in the literature¹ and do not require a profound theoretical understanding of sound propagation. They will only be briefly reviewed here.

Subjective assessment of noise is very useful because the human ear and brain can distinguish

between different sounds more precisely than the most sophisticated measurement system. With practice, an operator can tell by its sound if a machine is malfunctioning; a noise consultant can accurately estimate the blade passage frequency of a fan. In identifying sources, we should always listen to a machine first. To localize the sources and cut out extraneous noise, stethoscopes can be used or a microphone-amplifier-earphone system. Such a system also sometimes allows one to position the microphone near a source in an inaccessible or dangerous place where the human ear cannot reach. Chapter 67 discusses the subjective assessment of sound. In fact, humans can discern small differences in machine sounds that sometimes pose difficult tasks for sophisticated analysis equipment.

Selective operation of a complicated machine is often very useful. As long as the operation of a machine is not severely changed by disconnecting some of the parts sequentially, such a procedure can indicate the probable contribution of these parts to the total machine noise, when all parts are operating simultaneously. For instance, engine noise can be measured with and without the cooling fan connected, and this can then give an estimate of the fan noise. Note, however, that if the fan noise is lower in level than the engine noise, the accuracy of the estimate will be poor. The fan noise estimate can be checked by driving the fan separately by a “quieted” electric motor or other device. We should be aware that in some cases disconnecting some parts may alter the operation of the other parts of the machine and give misleading results. An example is an engine driving a hydraulic transmission under load. Disconnecting the transmission will give a measure of the engine-structure radiated noise, provided the inlet

and exhaust noise are piped out of the measuring room and the cooling fan is disconnected. But note that in such a situation the engine is now unloaded, and its noise may be different from the loaded case. Also an unfueled engine may be driven by a quieted electric motor so that the so-called engine mechanical noise is measured and the combustion noise is excluded. However, in this procedure the mechanical forces in the engine will be different from the normal fueled running situation, and we cannot say that this procedure will give the "true" mechanical noise.

Selective wrapping or enclosure of different parts of a machine is a useful procedure often used. If the machine is completely enclosed with a tight-fitting sealed enclosure and the parts of the enclosure are sequentially removed exposing different machine surfaces, then, in principle, the noise from these different surfaces can be measured. This method has the advantage that it is not normally necessary to stop any part of the machine, and thus the machine operation is unchanged. However, some minor changes may occur if any damping of the machine surfaces occurs or because sound will now diffract differently around the enclosure.

Measurements of the sound power radiated from different surfaces of a diesel engine using this selective wrapping approach are discussed in Refs. 2 and 3. An array of 30 microphone positions on a spherical surface surrounding the engine was used for both the lead-wrapping and bare-engine sound measurements. Overall one-third octave sound pressure level data were gathered. These data were then converted to sound intensity estimates by assuming (1) spherical propagation, (2) no reflections, and (3) that the intensity is equal to the mean-square pressure divided by the air's characteristic impedance ρc . Then the sound intensity data were integrated numerically over the surface of the spherical measuring surface enclosing the engine to obtain the sound power. The lead was wrapped on the engine so that later a particular surface, for example, the oil pan, could be exposed. The one-third octave band results for the fully wrapped engine compared with the results for the bare engine at the 1500 Revolutions/minute (rpm) engine speed, 542-Nm torque operating condition are shown in Fig. 3a. This comparison shows that the lead wrapping is ineffective at frequencies at and below the 250-Hz one-third octave band.^{2,3}

Eight individual parts of the engine were chosen for noise source identification and ranking purposes using the measurement technique with the spherical microphone array and the engine lead wrapped.^{2,3} The measurements were made by selectively exposing each of the eight parts, one at a time, while the other seven parts were encased in the 0.8-mm foam-backed lead. Sound power level measurements were then made for each of the eight parts for three separate steady-state operating conditions.^{2,3} One-third octave band comparisons with the fully wrapped engine are shown in Figs. 3b and 3c for two of the eight parts at the 1500 rpm operating condition. These plots show that the sound power measurements using lead wrapping

are not always accurate for the weaker parts until the frequency exceeds 1000 Hz. A plot of the noise source ranking using overall sound power levels for the eight parts under investigation for the 315-Hz to 10-kHz one-third octave bands is given in Fig. 4.

Similar selective wrapping techniques have been applied to a complete truck (Fig. 5). Exhaust noise was suppressed with an oversize muffler, the engine was wrapped, and even the wheel bearings were covered! The results of this investigation⁴ are shown in Fig. 6a

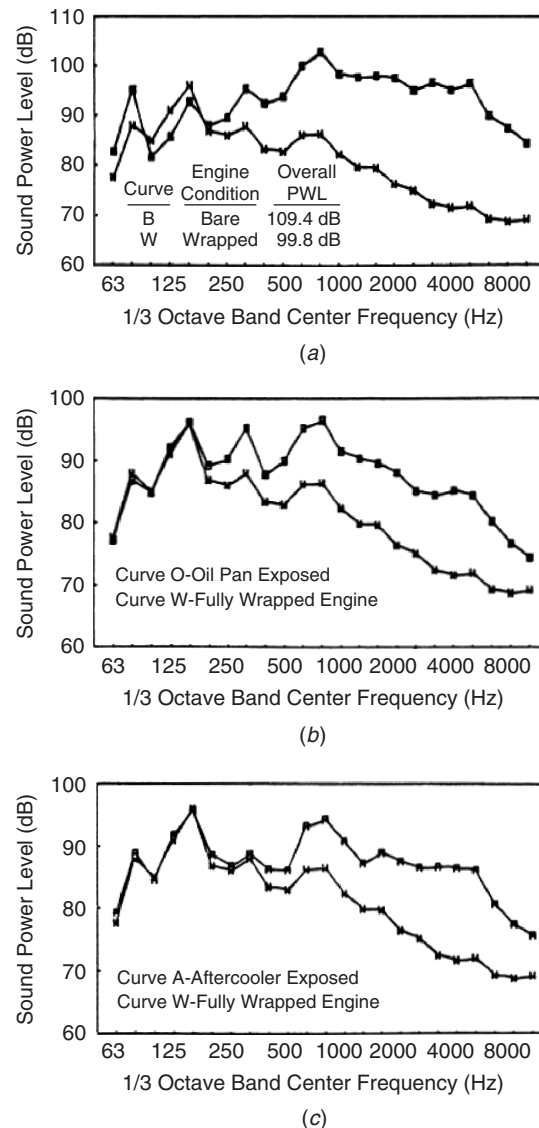

Figure 3 Sound power level of engine and parts at 1500 rpm and 542-Nm torque: (a) bare and fully wrapped engine, (b) oil pan and fully-wrapped engine, and (c) aftercooler and fully wrapped engine. (From Ref. 2.)

Figure 4 Noise source ranking in terms of sound power levels from lead-wrapping far-field spherical array method for the 315-Hz to 10-kHz one-third octave bands. (From Ref. 2.)

and 6b. Although the selective wrapping technique is very instructive, it is time consuming, and this has led to the search for other techniques that do not require complete enclosure, as described later.

5 FREQUENCY ANALYSIS

If the noise (or vibration) of either the complete machine or of some part (obtained by selective operation or sequential wrapping) is measured, then various analyses may be made of the data. The most

Figure 5 Selective wrapping and oversized muffler used on a diesel engine truck.

Figure 6 A-weighted sound pressure levels obtained from selective wrapping and selective operation techniques applied to truck in Fig. 5: (a) A-weighted one-third octave analysis and (b) A-weighted overall sound pressure level contributions of truck sources as a function of truck drive by position (in feet and metres). (From Ref. 4.)

common analysis performed is *frequency analysis*. The reason probably is because one of the most important properties of the ear is performing frequency analysis of sounds. Analog analyzers (filters) have been available for many years. These analog devices have now been largely overtaken by digital analyzers (filters). Real-time analyzers and fast Fourier transform (FFT) analyzers are now widely available.

Real-time and FFT analyzers speed up the frequency analysis of the data, but because of the analysis errors that are possible (particularly with the FFT) great care should be taken. With FFT analyzers, antialiasing filters can be used to prevent frequency folding; and if reciprocating machine noise is analyzed, the analysis period must be at least as long as the repetition period (or multiples) to incorrect frequencies being diagnosed. Chapter 42 deals in detail with signal processing, while Chapter 40 reviews the use of different types of filters and the FFT technique and other related topics. Chapter 43 reviews noise and vibration measurements.

Assuming the frequency analysis has been made correctly, then it can be an important tool in identifying

noise sources. With reciprocating and rotating machinery, pure tones are found that depend on the speed of rotation N in rpm, and geometrical properties of the systems. As discussed in Chapter 68, several frequencies can be identified with rolling-element bearings,⁵ including the fundamental frequency $N/60$ Hz, the inner and outer race flaw defect frequencies, and the ball flaw defect, ball resonance and the race resonance frequencies. Bearing noise is discussed further in Chapter 70. With gears, noise occurs at the tooth contact frequency $tN/60$ Hz and integer multiples (where t is the number of gear teeth). Often the overtone frequencies are significant. See Chapter 69. In fan noise, the fundamental blade-passing frequency $nN/60$ (where n is the number of fan blades) and integer multiples are important noise sources. See Chapter 71.

Further machine noise examples could be quoted. Since these frequencies just mentioned are mainly proportional to machine rotational speed, a change of speed or load will usually immediately indicate whether a frequency component is related to a rotational source or not. A good example of this fact is diesel engine noise. Figure 7a shows the time history and power spectrum of the cylinder pressure of a six-cylinder direct injection engine,⁶ measured by Seybert. Ripples in the time history are thought to be caused by a resonance effect in the gas above the piston producing a broad peak in the frequency spectrum in the region of 3 to 5 kHz. See Fig. 7b. That this resonance frequency is related to a gas resonance and not to the rotational speed can clearly be demonstrated. If the engine speed is changed, the frequency is almost unchanged (for constant load); although if the load is increased (at constant speed) the frequency increases. On further investigation the resonance frequency was found to be proportional to the square root of the absolute temperature of the gas (the gas temperature increases with load) and thus as the load increases, so does the resonance frequency.

Frequency analysis can sometimes be used with advantage to reveal information about noise or vibration sources and/or paths by carefully changing the source or the path in some controlled way. The following discussion gives some examples for an air conditioner and an airplane.

5.1 Change of Excitation Frequency

As already discussed, information on sources of noise and resonances in a diesel engine can be obtained when the load (and speed) are changed. In some cases (e.g., electrical machines) changing speed is difficult. In the case of the noise from an air conditioner, mechanical resonances in the system can be important.⁷ These can be examined by exciting the air conditioner structure at different frequencies with an electromechanical shaker. However, this means changing the mechanical system in an unknown way. The approach finally adopted in Ref. 7 was to drive the air conditioner electric motors with an alternating current (ac) that could be varied from 50 to 70 Hz from a variable-speed direct current (dc) motor-AC generator set. Since the noise problem was caused by pure-tone magnetic force

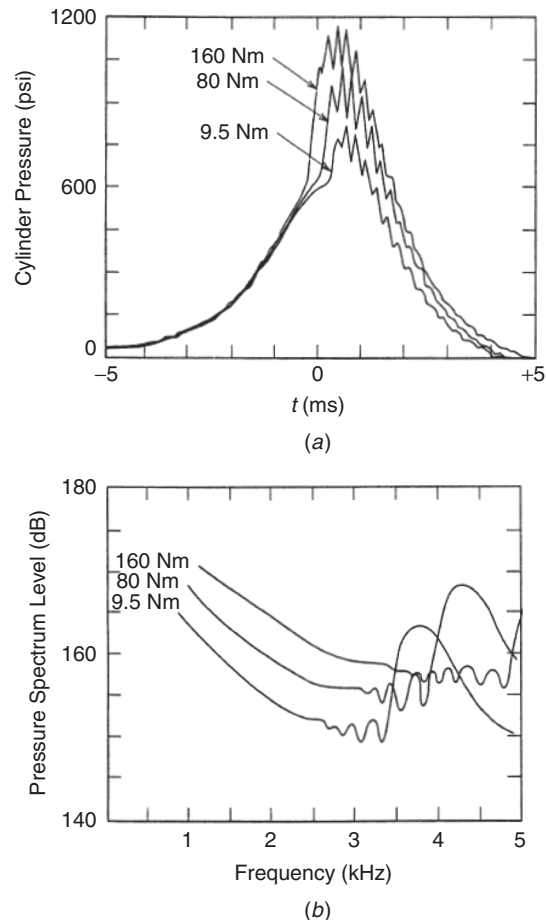

Figure 7 (a) Diesel engine cylinder combustion pressures vs. crank angle for three diesel engine load conditions at 2400 rpm and (b) combustion pressure spectra at 2400 rpm. P_a . (From Ref. 6.) Note: Pressure of 1 psi $\equiv 6.89 \times 10^3 P_a$.

excitation at twice line (mains) frequency, this was monitored with a microphone at the same time as the motor acceleration. Figure 8 shows the results. This experiment showed that the motor mounts were too stiff. Reducing the stiffness eliminated the pure-tone noise problem. Hague⁸ has shown how this technique can be improved further in air-handling systems by using an electric motor in which rotational speed, line frequency, and torque magnitude (both steady and fluctuating) can be varied independently.

In the case just discussed with the air conditioner, it was shown that the transmission path was through the motor mount (which was too stiff). In cases where airborne and structure-borne noise are both known to be problems and the source is known (an engine), the dominant path can sometimes be determined quantitatively by cutting one or more of

Figure 8 Sound pressure level and motor acceleration of condenser fan. (From Ref. 7.)

the paths or by modifying the paths in a known way. Examples include engine noise problems and airborne and structure-borne transmission in cars, farm tractors, and airplanes.

5.2 Path Blocking

One example is shown here of the evaluation of the structure-borne path of engine noise transmission by detachment of the engine from the fuselage in ground tests.⁹ Figure 9 shows the A-weighted sound pressure levels of the cabin noise with and without the engine connected to the fuselage. When the engine was detached, it was moved forward about 5 cm to prevent any mechanical connections. The overall reduction of 3 dB suggests that the contributions of airborne and

structure-borne noise to the cabin noise are about equal for this situation. There is a variation in the structural noise contribution with frequency, however, and at some frequencies the structure-borne contribution is seen to exceed the airborne contribution. McGary has presented a method of evaluating airborne and structure-borne paths in airplane structures.¹⁰

Airborne paths can be reduced or “blocked” by the addition of lead sheets or mass-loaded vinyl sheets of 5 to 10 kg/m². Figure 10, for example, shows areas of the cabin walls of airplanes that were covered to reduce the airborne transmission.¹¹

The spectrum of the noise in the cabin of a light twin-engine airplane is shown in Fig. 11. Discrete frequency tones associated with the blade passage frequency and harmonics are evident with the first two being dominant. The broadband noise at about 70 dB is associated with boundary layer noise. The tone at about 670 Hz can be related to the engine turbine speed and suggests the presence of engine-generated structure-borne noise.¹²

6 OTHER CONVENTIONAL METHODS OF NOISE SOURCE IDENTIFICATION

Acoustical ducts have been successfully used by Thien¹³ as an alternative to the selective wrapping approach (see Fig. 12). One end of the duct is carefully attached to the part of the machine under examination by a “soundproof” elastic connection. Nakamura and Nakano have also used a similar approach to identify noise sources on an engine.¹⁴ Thien has claimed that accurate repeatable results can be obtained using this method.¹³ However, one should note various difficulties. Sealing the duct to the machine may be difficult. The surroundings should be

Figure 9 Determination of structure-borne engine noise by engine detachment. (From Ref. 9.)

Figure 10 Surfaces of airplane walls covered to aid in identifying importance of airborne and structure-borne paths. [From Ref. 11, based on figures from V. L. Metcalf and W. H. Mayes, Structure Borne Contribution to Interior Noise of Propeller Aircraft, *SAE Trans.*, Sect. 3, Vol. 92, 1983, pp. 3.69–3.74 (also SAE Paper 830735), and S. K. Jha and J. J. Catherines, Interior Noise Studies for General Aviation Types of Aircraft, Part II: Laboratory Studies, *J. Sound Vib.*, Vol. 58, No. 3, 1978, pp. 391–406, with permission.]

Figure 12 Acoustical duct used to identify sources.

made as anechoic as possible to prevent contamination from any reverberant field. Theoretically the duct may alter the acoustic radiation from the machine part examined except for the frequency region much above coincidence. Fortunately this frequency region is normally the most important one with heavy machinery, and since in this region radiation is mainly perpendicular to the surface, it may be little affected in practice.

Acoustical ducts or guides have also been used to investigate paths of noise. Figure 13 shows an example where airborne noise was directed onto the cabin wall of a light airplane. The noise reduction through the wall of the airplane was measured and compared with theory. Note that the noise reduction here is defined to be the difference between the outside sound pressure level, SPL_o , and the inside sound pressure level, SPL_i . The agreement between the experimental

results and the theoretical model theory was excellent at frequencies below about 250 Hz.¹⁵

Near-field measurements are very often used in an attempt to identify major noise sources on machines. This approach must be used with extreme care. If a microphone is placed in the acoustic near field where kr is small (k is the wavenumber $= 2\pi$ frequency $f \div$ wavespeed c , and r is the source to microphone distance), then the sound intensity is not proportional to sound pressure squared, and this approach gives misleading results. This is particularly true at low frequency. The acoustic near field is reactive: The sound pressure is almost completely out-of-phase with the acoustic particle velocity.

Thus, this near-field approach is unsuitable for use on relatively "small" machines such as engines. However, for "large" machines such as vehicles with several major sources including an engine cooling fan, exhaust, or inlet, the near-field approach has proved useful.¹⁶ In this case where the machine is large, of characteristic

dimension l (length or width), it is possible to position the microphone so that it is in both the near geometric field, where r/l is small, and the far acoustic field, where kr is reasonably large (except at low frequency). In this case the microphone can be placed relatively close to each major noise source. Now the sound intensity is proportional to the square of the sound pressure, and the well-known inverse square law applies. Besides the acoustic near-field effect already mentioned, there are two other potential problems with this approach: (i) source directivity and the need to use more than one microphone to describe a large noise source and (ii) contamination of microphone sound signals placed near individual sources by sound from other stronger sources. Unfortunately, *contamination* cannot be reduced by placing the microphones closer to the sources because then the acoustic near field is stronger. However, *contamination* from other strong sources can be allowed for by empirical correction using the inverse square law and the distance to the contaminating source.

Despite the various potential problems with the near-field method, it has been used quite successfully to identify the major noise sources on a large diesel engine truck.¹⁶ By placing microphones near each major noise source (Fig. 14) and then extrapolating to a position 50 ft (14.5 m) from the truck (Fig. 15), good agreement could be obtained with separate *selective operation* and *selective wrapping* drive-by measurements (Fig. 16). Averaging over five positions near each source and correcting for contaminating sources gave quite close agreement (Fig. 17).

Surface velocity measurements have been used by several investigators to try to determine dominant sources of noise on engines and other machines. The sound power W_{rad} radiated by a vibrating surface of area S is given by

$$W_{\text{rad}} = \rho c S \langle v^2 \rangle \sigma_{\text{rad}} \quad (1)$$

where ρc is the characteristic impedance of air, $\langle v^2 \rangle$ is the space-average of the mean-square normal surface velocity, and σ_{rad} is the radiation efficiency. Chan and Anderton¹⁷ have used this approach. By measuring the sound power and the space-averaged mean-square velocity on several diesel engines, they calculated the radiation efficiency σ_{rad} . They concluded that above 400 Hz, σ_{rad} is approximately 1 for most diesel engines. There is a scatter of ± 6 dB in their results, although this is less for individual engines. Since σ_{rad} is difficult to calculate theoretically for structures of

Figure 15 Position (in feet) of truck (in Fig. 14) in drive-by test when truck engine reached its governed speed of 2100 rpm in sixth gear.¹⁶ Extrapolations to 50 ft (14.5 m) measurement location shown. (LHS = left-hand side, RHS = right-hand side. Distances are given in feet. Note: 1 ft = 0.3048 m).

Figure 16 Near-field noise measurements (shown in Figs. 14 and 15) extrapolated to 50 ft (14.5 m) for comparisons with drive-by noise source identification procedure based on SAE J366a test. The near-field distances are given in feet. (From Ref. 16.)

Figure 17 Engine noise at 50 ft (14.5 m) predicted from near-field measurements (see Fig. 16) after corrections are made to eliminate the contribution from the exhaust system noise, compared with the drive-by result. (From Ref. 16.)

complicated geometry such as a diesel engine, the assumption that $\sigma_{\text{rad}} = 1$ can thus give an approximate idea of the sound power radiated by each component.

Mapping of the sound pressure level around a machine has been shown¹⁸ to be a useful simple

procedure to identify major noise sources. For sources radiating hemispherically, it is easy to show that the floor area within a certain level contour is proportional to the sound power output of the machine. This method is graphic and probably more useful to identify the noisiest machines in a workshop than the noisiest parts on the same machine, because of the contamination problems between different sources in the latter case. Reverberation in a workshop will affect and distort the lower sound pressure level contours.

7 USE OF CORRELATION AND COHERENCE AND TECHNIQUES TO IDENTIFY NOISE SOURCES AND PATHS

Correlation and coherence techniques in noise control date back over 50 years to the work of Goff¹⁹ who first used the correlation technique to identify noise sources. Although correlation has often been used in other applications, it has not been widely used in noise source identification. One exception is the work of Kumar and Srivastava, who reported some success with this technique in identifying noise sources on diesel engines.²⁰ Since the ear acts as a frequency analyzer, the corresponding approach in the frequency domain (coherence) instead of the time domain is usually preferable. Crocker and Hamilton have reviewed the use of the coherence technique in modeling diesel engine noise.²¹ Such a coherence model can also be used, in principle, to give some information about noise sources on an engine. Figure 18 shows an idealized model of a multiple-input, single-output system. It can be shown²² that the autospectrum of the output noise S_{yy} is given by

$$S_{yy} = \sum_{i=1}^N \sum_{j=1}^N S_{ij} H_i H_j^* + S_{zz} \quad (2)$$

where N is the number of inputs, S_{ij} are cross-spectral densities between inputs, H_i and H_j are frequency

Figure 18 Multiple-input, single-output system with uncorrelated noise $z(t)$ in output.

responses, and S_{zz} is the autospectral density of any uncorrelated noise z present at the output. Note that the asterisk represents complex conjugate and that the S and H terms are frequency dependent.

If there are N inputs, then there will be N equations:

$$S_{iy} = \sum_{j=1}^N H_j S_{ij}, \quad i = 1, 2, 3, \dots, N \quad (3)$$

The frequency responses $H_1, H_2, H_3, \dots, H_N$ can be found by solving the set of N equations (3).

Several researchers have used the coherence approach to model diesel engine noise.²¹⁻²⁴ This approach appears to give useful information on a naturally aspirated diesel engine, which is combustion-noise dominated and where the N inputs x_1, \dots, x_N , are the cylinder pressures measured by pressure transducers in each cylinder. In this case H_i , the frequency response (transfer function) between the i th cylinder and the far-field microphone can be calculated. Provided proper frequency averaging is performed, the difficulty of high coherence between the cylinder pressures can be overcome because the phasing between the cylinder pressures is exactly known.²⁵ In this case the quantity $S_{ii}|H_i|^2$ may be regarded as the far-field output noise contributed by the i th cylinder. This may be useful noise source information for the engine designer. Hayes et al.²⁶ in further research have extended this coherence approach to try to separate combustion noise from piston-impact noise in a running diesel engine.

Wang and Crocker showed that the multiple coherence approach could be used successfully to separate the noise from sources in an idealized experiment such as one involving three loudspeakers, even if the source signals were quite coherent.^{27,28} However, when a similar procedure was used on the more complicated case of a truck, which was modeled as a six-input system [fan, engine, exhaust(s), inlet, transmission], the method gave disappointing results and the simpler near-field method appeared better.^{16,27} The partial coherence approach was also used in the idealized experiment and the truck experiments. It is believed that contamination between input signals and other computational difficulties may have been responsible for the failure of the coherence method in identifying truck noise sources.

8 USE OF SOUND INTENSITY FOR NOISE AND VIBRATION SOURCE AND PATH IDENTIFICATION

Studies have shown that sound intensity measurements are quicker and more accurate than the selective wrapping approach in identifying and measuring the strength of noise sources.³ The sound intensity I is the net rate of flow of acoustic energy per unit area. The intensity I_r in the r direction is

$$I_r = \langle pu_r \rangle \quad (4)$$

where p is the instantaneous sound pressure, u_r is the instantaneous acoustic particle velocity in the r direction, and the angle brackets denote a time average. The sound power W radiated by a source can be obtained by integrating the component of the intensity I_n normal to any surface enclosing the source:

$$W = \int I_n dS. \quad (5)$$

The sound pressure p and particle velocity are normally determined with two closely spaced microphones (1 and 2) and the surface S is a surface enclosing the source. Chung first used this technique with the surface of a diesel engine subdivided into $N = 98$ radiating areas.²⁹ It took about 2 min to determine the surface-average sound intensity radiated from each of the 98 areas. The engine was source identified in less than a day, which involved much less time than the selective wrapping technique. Since the intensity measurements were made only 20 mm above the engine surfaces, an anechoic or semianechoic room was unnecessary. Many other researchers have used similar sound intensity approaches to identify noise sources since then, as is discussed in more detail in Chapter 45.

9 TRANSFER PATH AND NUMERICAL ACOUSTICS

Recently, methods have been extended and adapted in a variety of ways to produce improved approaches for noise and vibration source and path identification.^{54–75} One example is the so-called transfer path analysis (TPA) approach⁶⁹ and variations of it, which is to some extent based on an elaborated version of the earlier coherence approach to source and path modeling as was outlined in Section 7.^{21–29}

Transfer path analysis is a procedure based on measurements and has been developed to allow tracing the flow of vibration and acoustic energy from sources, through a set of structure- and airborne pathways, to a given receiver location. In cases where multiple partially correlated sources exist, it is usually necessary to use airborne source quantification techniques as well as vibration source quantification techniques.⁶⁹

In the TPA approach, the vector contribution of each path of energy from the source to the receiver is evaluated, so that the components along each path, which need modification, can be identified. The measurements are normally time consuming since several hundred frequency response functions (FRFs) may need to be acquired. The measurements are also difficult to perform because of the limited space available for transducers. In addition, large amounts of data are generated requiring careful data storage and management.

In complicated structures, which involve many sub-assemblies such as are found in complex machines, automobiles, buses, aircraft, and ships, the sound and vibration energy reaching a point will have been caused by some sound and vibration sources situated

close to and others further away from that particular location. TPA is used to assess the structure- and airborne energy paths between excitation source(s) and receiver location(s). For example, structure-borne energy from sources in an automobile is transmitted into the passenger cabin by several different paths, including the engine mounts, the exhaust system connection points, the drive shaft, and the wheel suspension system. Airborne contributions from sources, including the tires, the intake and exhaust systems, regions of separated airflow, and the like are also important. Some transfer paths may result in standing waves in the cabin and produce noise problems at some locations but not at others.

Figure 19 illustrates noise and vibration sources in an automobile.⁶⁹ P is an observation point. Three source locations are shown; one is a source of volume velocity Q_i and the other two are vibration sources caused by force inputs, f_i . A transfer function H_{pi} between a source i and the observation point P is shown.

In the case of the booming noise problem, the receiver sound can be measured in the car during engine runup by microphones located at the same position as the occupants' ears. An example of a measurement of the sound pressure amplitude as a function of frequency, made in a car during the idle runup of its 24-valve, 6-cylinder engine, is shown in Fig. 20. Clear (and annoying) booming effects are evident in the 1.5-engine order with a boom between 3000 and 4000 rpm, and another high-frequency boom around 5000 rpm (Fig. 21). In the third order there is a boom around 5000 rpm. The 0.5-engine order seems to be very important, although in practice it does not significantly affect acoustical comfort. The TPA approach can be used to study the sources and paths of such booming noise on more detail.⁶⁹

In transfer path analysis, the receiver and sources are normally considered to consist of two different subsystems. In structure-borne transfer path analysis, the two subsystems are assumed to be connected by several quite stiff connections—called the transfer paths.

Figure 19 Airborne and structure-borne transfer paths in a vehicle. (From Ref. 69.)

Figure 20 Waterfall diagram of sound pressure amplitude as a function of frequency at the driver's ear as the engine speed is changed from 1200 to 6000 rpm. (From Ref. 69.)

Figure 21 Order sections. Overall level —; 0.5th order —●—; 1.5th order - - -; 3rd order —■—. (From Ref. 69.)

The primary transfer paths to be analyzed include paths through elements such as the engine support mounts, the transmission shaft supports, gearbox mounts, sub-frame mounts, and exhaust system connections. Secondary transfer paths will exist as well passing through the shock absorber and gear shift mounts. In airborne transfer path analysis, the transfer paths include the engine intake and exhaust pipes and the vibrating panels in the car interior. TPA requires knowledge of the frequency response functions between the receiver and

the inputs (forces or volume velocities) applied at the different source locations, and combines them with inputs (forces or volume velocities) that are active at these locations during vehicle operation. The receiver sound pressure level (or acceleration level, if appropriate) during operating conditions is then calculated from the summation of individual path contributions.⁶⁹

Vibration and acoustical transfer functions are usually measured using either hammer or shaker excitation techniques. The acoustical transfer functions (from input volume velocity to output sound pressure) are normally measured using volume velocity source excitation techniques. The operational inputs (forces or volume velocities) are determined from (1) experimental data, (2) from analytical models, or (3) from indirect measurements. Three data sets are needed: (1) operating data (forces, volume velocities, accelerations, sound pressures), (2) frequency response functions [acoustical frequency response functions (FRFs) and/or accelerance FRFs], and (3) complex dynamic stiffness data for the mounts. Accelerance is defined as the output acceleration spectrum divided by the input force spectrum.⁶⁹

The operating data are often acquired at more locations than there are channels available in the measurement system. To preserve phase information between channels, it is important to perform all measurements in relation to one reference measurement channel. For applications such as an operating automobile engine, a suitable reference signal can be obtained from an accelerometer mounted on the engine. For steady-state applications, cross-power measurements must be made with respect to the single reference channel. For non-stationary applications, the referenced measurements are processed to extract a set of selected order sections as functions of engine rpm. Source-receiver transfer functions are required for all transfer paths. At the receiver side of all of the transfer paths (often referred to as body-side transfer paths) either hammer impact or shaker excitation is normally used to measure the corresponding accelerance frequency response function. A volume velocity source can be used to measure the acoustical frequency response functions.

The vibration frequency response functions (between force and sound pressure) can either be measured in a direct way using hammer or shaker excitation or in a reciprocal way using a volume velocity source. These FRFs are measured best when the source side is disconnected from the receiver side of the transfer path. Measuring the body-side FRFs is a critical element in transfer path analysis. In practice there is usually little physical space between the engine and engine mount in which to locate the force transducers. In principle, the engine should be removed while the other side of the engine transfer path system is analyzed. A common approach is to remove the engine to gain access to the body side of the mount directly and to use a hammer or shaker to excite the system directly. In the same way, ideally, the suspension should be removed when measuring body-side FRFs that are related to road noise.⁶⁹

The operating forces are usually estimated by indirect techniques, rather than direct measurements. Two alternative approaches are often used: the *complex stiffness method* and *matrix inversion*. For some transfer paths, the complex dynamic stiffness method is recommended. For others, because the mount stiffness data are not available, or the differential operating displacement over the connection is small, or because the connection is quite rigid, other approaches must be used.

For transfer paths where the source side is connected to the receiver by mounts, the operating forces can be determined from knowledge of the complex frequency-dependent dynamic stiffness of the mounts and by determining the differential displacement over the mount during operation. The displacements are usually derived from acceleration measurements.

The complex dynamic mount stiffnesses should be determined as complex data functions of frequency. These can be assumed to be positive: either in tension or in compression. The mount characteristics can be expressed in terms of force–displacement, force–velocity, or force–acceleration. When evaluating the dynamic stiffness of mounts, it is important to preload them so that they function near to the actual operating conditions.

For transfer paths comprised of rigid connections, or where the mount stiffness is very large relative to the body impedance, inducing even a small relative displacement over the mount is not possible. In such cases, a technique based upon inversion of a measured accelerance matrix between structural responses on the receiver side due to force excitation at all transfer paths can be used. This accelerance matrix must be measured when the source is disconnected from the receiver. This matrix is then combined with measurements of the structural vibration at the receiver side to obtain force estimates. The use of singular value decomposition methods helps to minimize numerical problems in the matrix inversion.⁶⁹

When applying the accelerance matrix inversion method, receiver-side vibrations usually must be measured in three directions in operating conditions. To obtain a unique solution for the operational forces, the number of responses (m) should at least be equal to the number of input forces to be estimated (n). However, more response measurements can be taken at the receiver side ($m > n$), since the measurement locations are not restricted to the transfer path locations. The TPA approach is crucially dependent on good estimates of the input forces, volume velocities, and transfer paths. Figure 22 shows how different methods can be used to estimate input forces.⁶⁹ The agreement between the three methods is seen to be better for low than high engine speeds.

Airborne transfer paths are normally quantified by their input volume velocities. These volume velocities are usually estimated from indirect techniques, in a similar way to the input forces. Three techniques are available: (1) point-to-point surface sampling, (2) sound intensity measurements, and (3) matrix

Figure 22 Comparison of operational forces at a car body. 1: +Z path, third order. Measured force via force transducer —■—; force estimated via complex dynamic stiffness method - - -; force estimated via matrix inversion method —■— (From Ref. 69.)

inversion. This first method is used to determine contributions from vibrating panels. The second can be used to determine the airborne contributions from an engine. A typical application of matrix inversion is to quantify the intake and exhaust noise.⁶⁹

10 INVERSE NUMERICAL ANALYSIS APPROACH FOR SOURCE IDENTIFICATION

Other studies, which are similar to the TPA approach, have shown that numerical acoustics techniques can be used for source identification.^{70–75} The approach described here is usually called inverse numerical analysis (INA) and is similar to the acoustical holography method described in Chapter 50. In TPA, the main concern is determining the exciting forces (e.g., the forces supplied by an engine through the engine mounts), while with INA the main concern is to reconstruct the surface vibration of an acoustic source. So, fundamentally, the objectives of TPA and INA are different.

The main difference between TPA and INA lies in the determination of the transfer functions, H . In TPA, these are usually obtained by experiment (e.g., the actual sources are turned off or disconnected, and a shaker is used in place of each vibration source in a sequential fashion). In INA, each transfer function, H , is defined as the ratio of the sound pressure at a point in the near field of the source to the vibration velocity at a point on the surface of the source; the acoustical transfer vector (ATV) is simply a row of these transfer functions between a given point in the near field and each surface point; ATM is a matrix in which each row is the ATV for each field point. Because the number of surface points can be in the thousands, the transfer functions are usually obtained from a boundary element model (BEM) model (although, in principle, transfer functions can be measured either directly or using reciprocity). Thus, INA is a model-based method

in which a BEM model is used to obtain the transfer functions.⁷⁶

What is common to both methods is that they both require an inversion of a matrix of transfer functions. With TPA there are normally more equations than unknowns, so the system is overdetermined; with INA there are more unknowns than equations, so the system is underdetermined.

The starting point for the INA approach is the acoustical transfer vector (ATV). ATVs can be used in two different ways. First, ATVs can be used to conduct contribution analyses that can assess which parts of a machine act as the predominant noise sources. For example, the sound power contribution and radiation efficiency of different parts of an engine can be calculated if the distribution of the normal velocity on the surface is known. Additionally, ATVs can be used to reliably reconstruct the vibration on a machine surface. This procedure utilizes measured sound pressures along with ATVs to reconstruct the surface velocity.

Fahy demonstrated that ATVs can be measured, and perhaps ATVs can best be understood using the concept of acoustical reciprocity, which he has explained.⁷¹ Figure 23 illustrates this concept by comparing a direct and corresponding reciprocal case. For the situation shown in Fig. 23,

$$\frac{p_1}{v_n \delta S} = \frac{p_2}{Q} \quad (6)$$

where p_1 and p_2 are sound pressures, v_n is the normal velocity on the surface, δS is a differential area, and Q is the volume velocity of a point source. The right hand or the corresponding left hand side of Eq. (6) is a single element of an ATV. Thus, the row vector obtained by finding this ratio at each point or node on a radiating surface is the fully populated ATV at a given frequency. It follows that another ATV will be required for each sound pressure measurement location in the sound field. It should be apparent that ATVs can be measured most readily using the reciprocal approach (Fig. 23) since it is easier to traverse a microphone over the surface of a machine rather than some known sound source. Figure 24 shows how such measurements can be realized in practice.⁶⁹

Figure 23 Schematic showing the principle of acoustical reciprocity. (From Ref. 70.)

Figure 24 Measurement of inverse transfer functions using the reciprocal approach. (From Ref. 69.)

If an appropriate numerical model can be produced, ATVs are more easily calculated than measured and really do not require any knowledge about the source except for the geometry and the location of any sound-absorbing materials that may be present. As mentioned previously, in principle, several different numerical methods could be used to calculate ATVs, although the BEM has generally been the method of choice. Because the number of surface points can be in the thousands, the transfer functions are usually obtained from a BEM model (although these transfer functions can be measured either directly or by using reciprocity). The sound pressure at a field point (p_f) can be related to any surface vibration (v_n) via

$$p_f = [H_{fn}] \{v_n\} \quad (7)$$

Here the acoustical transfer vector $[H_{fn}]$ represents a row of transfer functions H_{fn} . For multiple field points, Eq. (7) can be written in matrix form as

$$\{p_f\} = [H_{fij}] \{v_n\} \quad (8)$$

where H_{fij} are elements of the acoustical transfer matrix, $[H_{fij}]$ or ATM. The ATM is a collection of ATVs for different points in the field.

Inverse numerical acoustics (INA)⁷⁰⁻⁷⁵ is the process of solving Eq. (8) in the reverse direction. The sound pressures at the field points (p_f) are the known quantities, whereas the surface vibrations (v_n) are the unknowns. In most cases, there are far more unknown vibrations than there are known or measured sound pressures. Thus, the problem could be classified as an underdetermined problem. Once the vibration on the surface is reconstructed, the characteristics of the vibrating source can be examined.

1 INTRODUCTION

Acoustical enclosures are used wherever containment or encapsulation of the source or receiver is a good, cost-effective, feasible solution. An enclosure corresponds to a noise control measure in the path. Often the main task is to keep the sound energy inside the enclosure and dissipate it by means of sound absorption. In some cases such as with personnel booths or automobile or aircraft cabins, the main task is to keep the noise outside and to absorb as much sound energy as possible that does penetrate the enclosure walls and come inside. Enclosures can be classified in five main types: (1) large loose-fitting enclosures in which complete machines are contained, (2) small enclosures used to enclose small machines or parts of large machines, (3) close-fitting enclosures that follow the contours of a machine or a part, (4) wrapping or lagging materials often used to wrap pipes, ducts, or other systems, and (5) large booths or room-sized enclosures and cabins in which personnel or vehicle passengers are contained.

The performance of enclosures can be defined in three main ways¹: (1) *noise reduction (NR)*, (2) *transmission loss (TL)*, or equivalently the *sound reduction index*, and (3) *insertion loss (IL)*. Enclosures can either be complete or partial (in which some walls are removed for convenience or accessibility). Penetrations are also often necessary for machine maintenance or to provide access during manufacture or for cooling.

The physical behavior and the efficiency of an enclosure depend mainly on: (1) the transmission loss of the walls of the enclosure, (2) its volume and necessary openings (access for passing materials in and out, ventilation and cooling, inspection windows, etc.), and (3) the sound energy absorbed inside the enclosure walls that are lined with sound-absorbing materials.

2 REVERBERANT SOUND FIELD MODEL FOR ENCLOSURES

In the energy model for an enclosure it is assumed that the reverberant sound field produced within the enclosure is added to the direct sound field produced

by the sound source being enclosed. The sum of the two sound fields gives the total sound field within the enclosure, which is responsible for the sound radiated by the enclosure walls.

If the smallest distance ℓ between the machine surface and the enclosure walls is greater than a wavelength λ ($\ell > \lambda$), for the lowest frequency of the noise spectrum of the machine (noise source), then the enclosure can be considered large enough to assume that the sound field within the enclosure is diffuse (the sound energy is uniformly distributed within the enclosure). Another criterion² used to assume the diffuse sound field condition requires the largest dimension of the interior volume of the enclosure to be less than $\lambda/10$.

Therefore, according to classical theory, the reverberant sound pressure level within the enclosure, L_{prev} , is given by^{3,4}

$$L_{prev} = L_W + 10 \log T - 10 \log V + 14 \quad (1)$$

where L_W is the sound power level of the source, T is the reverberation time within the enclosure in seconds, and V is the internal volume of the enclosure in cubic metres. Then, the reverberant sound intensity incident on the internal enclosure walls can be estimated from

$$I_i = \frac{\langle p^2 \rangle_{rev}}{4\rho c} \quad (2)$$

where $\langle p^2 \rangle_{rev}$ is the reverberant mean-square sound pressure (space-time average) within the enclosure, ρ is the density of the medium (air) within the enclosure, and c is the speed of sound.

3 MACHINE ENCLOSURE IN FREE FIELD

The sound field immediately outside an enclosure will consist of two components: (1) sound radiated due to the internal reverberant sound field and (2) sound radiated due to the direct sound field of the machine noise source. The fraction of sound energy that is incident on the interior of the enclosure wall that is transmitted depends on its transmission coefficient.

Figure 1 Acoustical enclosure placed in free field.

The transmission coefficient τ of a wall may be defined as

$$\tau = \frac{\text{sound intensity transmitted by wall}}{\text{sound intensity incident on wall}} \quad (3)$$

and this coefficient τ is related to the transmission loss (TL) (or sound reduction index) by

$$TL = 10 \log \frac{1}{\tau} \quad (4)$$

(See Chapter 54 for a definition and discussion of the transmission loss.)

If the enclosure is located in a free field, as shown in Fig. 1, the sound pressure level immediately outside the enclosure is^{3,4}

$$L_{p,ext} = L_{p,rev} - TL - 6 \quad (5)$$

Therefore, the enclosure with its noise source inside can be considered to be an equivalent sound source placed in free-field conditions. Now, if the floor is hard and highly reflective, the sound pressure level at a distance r from an enclosure wall can be estimated by

$$L_p(r) = L_{p,ext} + 10 \log S - 10 \log(2\pi r^2) \quad (6)$$

where S is the total outer surface area of the enclosure walls.

4 SIMPLE ENCLOSURE DESIGN ASSUMING DIFFUSE REVERBERANT SOUND FIELDS

If the sound fields are assumed to be reverberant both inside and outside a completely sealed enclosure (typical of a machine enclosure in a machine shop), then the noise reduction NR is given by

$$NR = L_{p1} - L_{p2} = TL + 10 \log \frac{A_2}{S_e} \quad (7)$$

where L_{p1} and L_{p2} are the reverberant sound pressure levels inside and outside the enclosure, $A_2 = S_2 \bar{\alpha}_2$ is the *absorption area* in square metres of the receiving space where $\bar{\alpha}_2$ is the surface average absorption coefficient of the absorption material in the receiving space averaged over the area S_2 , and S_e is the enclosure surface area in square metres. (See Chapter 57 for definitions and further discussion of absorption area A and Chapter 54 for a definition and discussion of transmission loss.)

4.1 Personnel Booth or Enclosure in a Reverberant Sound Field

Equation (7) can be used to design a personnel booth or enclosure in which the noise source is external and the reason for the enclosure is to reduce the sound pressure level inside (see Fig. 2). If the enclosure is located in a factory building in which the reverberant level is L_{p1} , then the enclosure wall TL and interior

Figure 2 Personnel enclosure placed in a reverberant sound field.

absorption area A_2 can be chosen to achieve a required value for the internal sound pressure level L_{p2} . In the case that the surface area S_2 of the internal absorbing material $S_2 = S_e$, the enclosure surface area, then Eq. (7) simplifies to

$$NR = TL + 10 \log \bar{\alpha}_2 \quad (8)$$

The NR achieved is seen to be less than the TL in general. When $\bar{\alpha}_2$, the average absorption coefficient of the absorbing material in the receiving space approaches 1, then NR approaches TL (as expected), although when $\bar{\alpha}_2$ approaches 0, then the theory fails.

Example 1 Consider that the reverberant level in the assembly area of a manufacturing shop is 85 dB in the 1600-Hz one-third octave band. It is required to provide values of TL and $\bar{\alpha}$ to achieve an interior level inside a personnel enclosure less than 60 dB. Assuming that $S_2 = S_e$, then if TL is chosen as 30 dB and $\bar{\alpha} = 0.2$, $NR = 30 + 10 \log 0.2 = 30 - 7 = 23$ dB, and $L_{p2} = 62$ dB. Now, if $\bar{\alpha}$ is increased to 0.4, then $NR = 30 + 10 \log 0.4 = 30 - 4 = 26$ dB and $L_{p2} = 59$ dB, meeting the requirement. Since TL varies with frequency [see Eq. (11)], this calculation would have to be repeated for each one-third octave band center frequency of interest. In addition, at low frequency, some improvement can be achieved by using a thicker layer of sound-absorbing lining material.

4.2 Machine Enclosure in a Reverberant Space

When an enclosure is designed to contain a noise source (see Fig. 3), it operates by reflecting the sound back toward the source, causing an increase in the sound pressure level inside the enclosure. From energy considerations the insertion loss is zero if there is no sound absorption inside. The effect is an increase in the sound pressure at the inner walls of the enclosure compared with the sound pressure resulting from the direct field of the source alone. The buildup of sound energy inside the enclosure, can be reduced by placing sound-absorbing material on the walls inside the enclosure. It is also useful to place sound-absorbing materials inside personnel noise protection booths for similar reasons.

The internal surfaces of an enclosure are usually lined with glass or mineral fiber or an open-cell polyurethane foam blanket. However, the selection of the proper sound-absorbing material and its containment will depend on the characteristics of each noise source. Sound absorption material also requires special protection from contamination by oil or water, which weakens its sound absorption properties. If the noise source enclosed is a machine that uses a combustible liquid, or gas, then the material should also be fire resistant. Of course, since the sound absorption coefficient of linings is generally highest at high frequencies, the high frequency components of any noise source will suffer the highest attenuation.

The effect of inadequate sound absorption in enclosures is very noticeable. Table 1 shows the reduction in performance of an ideal enclosure with varying degrees of internal sound absorption.⁴ The first column of Table 1 shows the fraction of internal surface area that is treated. The sound power of the source is assumed to be constant and unaffected by the enclosure.

For an enclosure that is installed around a source with a considerable amount of absorbing material used inside to prevent any interior reverberant sound energy buildup, then from energy considerations

$$IL \cong TL$$

if the receiving space is quite absorbent and if IL and TL are averaged over wide frequency bands (e.g., at least one octave). If insufficient sound-absorbing material is put inside the enclosure, the

70	-1.5

Figure 3 Machine enclosure placed in a reverberant environment.

sound pressure level will continue to increase inside the enclosure because of multiple reflections, and the enclosure effectiveness will be reduced. From energy considerations it is obvious that if there is no sound absorption inside ($\bar{\alpha} = 0$), the enclosure will be ineffective, and its insertion loss will be zero.

An estimate of the insertion loss for the general case $0 < \bar{\alpha} < 1$ can be obtained by assuming that the sound field inside the enclosure is diffuse and reverberant and that the interior surface of the enclosure is lined with absorbing material of surface-averaged absorption coefficient $\bar{\alpha}$. Let us assume that (1) the average absorption coefficient in the room containing the noise source is not greater than 0.3, (2) the noise source does not provide direct mechanical excitation to the enclosure walls, and (3) the noise source volume is less than about 0.3 to 0.4 of the enclosure volume, then we may show that the insertion loss of a loose-fitting enclosure made to contain a noise source situated in a reverberant space is⁵

$$IL = L_{p1} - L_{p2} = TL + 10 \log \frac{A_e}{S_e} \quad (9)$$

where L_{p1} is the reverberant level in the room containing the noise source (with no enclosure), L_{p2} is the reverberant level at the same location (with the enclosure), A_e is the absorption area inside the enclosure $S_i \bar{\alpha}_i$, and $\bar{\alpha}_i$ is the surface average absorption coefficient of this material. If the surface area of the enclosure $S_e = S_i$, the area of the interior absorbing material, then Eq. (9) simplifies to

$$IL = TL + 10 \log \bar{\alpha}_i \quad (10)$$

We see that normally the insertion loss of an enclosure containing a noise source is less than the TL. If $\bar{\alpha}_i$, the average absorption coefficient of the internal absorbing material approaches 1, the IL approaches TL (as expected), although when $\bar{\alpha}$ approaches 0, then this theory fails.

Example 2 Consider that the sound pressure level L_{p1} in a reverberant woodworking shop caused by a wood-planing machine in the 1600-Hz one-third-octave band in 90 dB. Then what values of TL and $\bar{\alpha}$ should be chosen to guarantee that the reverberant level will be less than 60 dB? Assuming that $S_i = S_e$, then if TL is chosen to be 40 dB and $\bar{\alpha} = 0.1$, $IL = 40 + 10 \log 0.1 = 40 - 10 = 30$ dB and $L_{p2} = 60$ dB. Now, if $\bar{\alpha}$ is increased to 0.2, then $IL = 40 + 10 \log 0.2 = 40 - 7 = 33$ dB and $L_{p2} = 57$ dB, thus meeting the requirement. As in Example 1, we can observe that since TL varies with frequency f [see Eq. (11)], this calculation should be repeated at each frequency of interest. At low frequencies, since large values of TL and $\bar{\alpha}$ are difficult to achieve, it may not be easy to obtain large values of IL.

Thus the TL can be used as an approximate guide to the IL of a sealed enclosure only when allowance is made for the sound absorption inside the enclosure. The transmission loss of an enclosure is usually mostly governed by the mass/unit area ρ_s of the

enclosure walls (except in the coincidence-frequency region). The reason for this is that when the stiffness and damping of the enclosure walls are unimportant, the response is dominated by inertia of the walls $\rho_s(2\pi f)$ where f is the frequency in hertz.

The transmission loss of an enclosure wall for sound arriving from all angles is approximately

$$TL = 20 \log(\rho_s f) - C \quad (11)$$

where ρ_s is the surface density (mass/unit area) of the enclosure walls and $C = 47$ if the units of ρ_s are kg/m² and $C = 34$ if the units are lb/ft². Equation (11) is known as the *field-incidence mass law*. The transmission loss of a wall [given by Eq. (11)] theoretically increases by 6 dB for each doubling of frequency or for each doubling of the mass/unit area of the wall.

Where the enclosure surface is made of several different materials (e.g., concrete or metal walls and glass), then the average transmission loss TL_{ave} of the composite wall is given by

$$TL_{ave} = 10 \log \frac{1}{\bar{\tau}} \quad (12)$$

where the average transmission coefficient $\bar{\tau}$ is

$$\bar{\tau} = \frac{S_1 \tau_1 + S_2 \tau_2 + \cdots + S_n \tau_n}{S_1 + S_2 + \cdots + S_n}, \quad (13)$$

where τ_i is the transmission coefficient of the i th wall element and S_i is the surface area of the i th wall element (m²).

5. OTHER MODELS FOR ENCLOSURES

In general, it is difficult to predict the insertion loss of an enclosure with a high degree of accuracy. This is because both the sound field inside and outside the enclosure cannot always be modeled using simple approaches. The models discussed so far are valid for large enclosures where resonances do not arise. However, in the design of enclosures at least two types of enclosure resonances have to be taken into account: (1) structural resonances in the panels that make up the enclosure and (2) standing-wave resonances in the air gap between the machine and the enclosure. At each of these resonance frequencies the insertion loss due to the enclosure is significantly reduced and in some instances can become negative, meaning that the machine with the enclosure may radiate more noise than without the enclosure. Therefore, the enclosure should be designed so that the resonance frequencies of its constituent panels are not in the frequency range where high insertion loss is required.

If the sound source being enclosed radiates predominantly low-frequency noise, then the enclosure panels should have high resonance natural frequencies, that is, the enclosure should be stiff and not massive. These requirements are very different from those needed for good performance of a single-leaf partition at frequencies below the critical frequency. To achieve a high

insertion loss in the stiffness controlled region, benefit can be gained by employing small panel areas, large panel aspect ratios, clamped edge conditions, and materials having a high bending stiffness.⁶

On the other hand, a high-frequency sound source requires the use of an enclosure with panels having low natural frequencies, implying the need for a massive enclosure. Additionally, the panels of the enclosure should be well damped. This would increase IL, in particular for frequencies near and above the critical frequency and at the first panel resonance.

In addition, mechanical connections between the sound source and the walls of the enclosure, air gap leaks, structure-borne sound due to flanking transmission, vibrations, and the individual radiation efficiency of the walls of the enclosure will reduce the IL in different frequency ranges.

For a sealed enclosure without mechanical connections between the source and the enclosure walls, the problem can be divided in three frequency ranges: (1) the low-frequency range, where the insertion loss is frequency independent and corresponds to frequencies below air gap or panel resonances, (2) the intermediate-frequency range, where the insertion loss is controlled by panel and/or air gap resonances that do not overlap so that statistical methods are not applicable, and (3) the high-frequency range, where high modal densities exist, consequently, statistical energy methods can be used for modeling. The insertion loss in the intermediate frequency region fluctuates widely with frequency and position and thus is very difficult to analyze by theoretical methods.^{2,7}

For a sealed, unlined, small rectangular acoustical enclosure, made of n separate, homogeneous, and isotropic panels, and where the sound field inside can be assumed as diffuse and reverberant, the insertion loss at very low frequencies is controlled by the volume compliance of the enclosure walls. Then the low-frequency insertion loss can be estimated by^{2,8}

$$IL = 20 \log \left[1 + \frac{VEh^3}{12 \times 10^{-3}(1 - \nu^2)\rho c^2} \times \sum_{i=1}^6 \frac{1}{S_i^3 F(z_i)} \right] \quad (14)$$

where V is the internal enclosure volume, E is the Young's modulus of the wall panels, h is the thickness of the wall panels, ν is the Poisson's ratio of the wall panels, S_i is the surface area of the i th wall panel, z_i is the aspect ratio (longest/smallest edge dimension) of the i th wall panel, and $F(z)$ is a function given by Lyon and plotted in Fig. 4, for both clamped and simply-supported edges.⁸ Equation (14) is valid for frequencies below the first mechanical resonance of the enclosure wall panels.

If the enclosure is a cube made of clamped panels of edge length a , Eq. (14) simplifies to

$$IL = 20 \log \left[1 + 41 \left(\frac{h}{a} \right)^3 \frac{E}{\rho c^2} \right] \quad (15)$$

Figure 4 Panel volume compliance function $F(z)$ plotted vs. the aspect ratio z for clamped and simply supported edges.⁸ (Reproduced with permission of American Institute of Physics.)

For a large, lined, unsealed, machine-mounted acoustical enclosure, made of N separate, homogeneous, and isotropic panels, and where the sound field inside can be assumed as diffuse and reverberant, the insertion loss at high frequencies can be calculated using a statistical energy analysis model presented by Ver.^{2,9} The insertion loss can be written as (adapting the notation of reference¹⁰)

$$IL = 10 \log \frac{\sum_{i=1}^7 S_{ai}}{S_{a2} + S_{a7} + S_{a8} + \frac{W_{SB}}{W_0} \sum_{i=1}^7 S_{ai}} \quad (16)$$

where W_0 is the sound power radiated by the unenclosed machine and the other terms in Eq. (16) are defined in Table 2.

In the equations in Table 2, S_w is the total interior wall surface area, α_w is the average energy absorption coefficient of the walls, S_{wi} is the surface area of the i th wall, TL_{wi} is the sound transmission loss of the i th wall, $S_i \alpha_i$ is the total absorption area in the interior of the enclosure in excess of the wall absorption (i.e., the machine body itself), S_{sk} is the face area of the k th silencer opening (assumed completely absorbent), m is the attenuation constant for air absorption, V is the volume of the free interior space, S_{Gj} is the area of the j th leak or opening, TL_{Gj} is the sound transmission loss of the j th leak or opening, ΔL_k is the sound

Table 2 Definition of Terms Used in Eq. (16)

Physical Meaning	Term	Equation ^a
Power dissipation by the wall absorption	$S_{\alpha 1}$	$S_w \alpha_w$
Power loss due to sound radiation of walls	$S_{\alpha 2}$	$\sum_i S_{wi} 10^{-TL_{wi}/10}$
Power dissipation in walls through damping	$S_{\alpha 3}$	$S_w D$
Power dissipation by sound-absorbing surfaces in addition to the walls	$S_{\alpha 4}$	$S_j \alpha_j$
Sound power loss due to silencers	$S_{\alpha 5}$	$\sum_k S_{sk}$
Sound absorption in air	$S_{\alpha 6}$	mV
Sound transmission to the exterior through gaps and openings	$S_{\alpha 7}$	$\sum_j S_{Gj} 10^{-TL_{Gj}/10}$
Sound power transmitted through silencers	$S_{\alpha 8}$	$\sum_k S_{sk} 10^{-\Delta L_k}$
Sound power transmitted through structure-borne paths	W_{SB}	$\sum_{i=1}^n F_i^2 \left(\frac{\rho}{\rho_s^2 c} + \frac{\rho c \sigma}{2.3 \rho_s^2 c_L h \omega \eta} \right)$
Force transmitted by the i th attachment point	F_i	$\frac{u_i}{ 1/2.3 \rho_s^2 c_L h + j\omega/s }$

^aDefinition of each term in the equations is given in the text.

attenuation through the k th silencer opening, ρ is the air density, ρ_s is the wall panel surface density, c is the speed of sound, σ is the radiation efficiency, c_L is the speed of longitudinal waves in the wall panel material, h is the wall panel thickness, $\omega = 2\pi f$, η is the loss factor of the wall panel, u_i is the vibration velocity of the machine at the i th attachment point, n is the total number of point attachments between the machine and the enclosure wall, $j = \sqrt{-1}$, s is the dynamic stiffness of the resilient mount connecting the wall to the machine ($s = \infty$ for rigid point connections), and D is a dimensionless term given by

$$D = \left(\frac{4\pi\sqrt{12}\rho c^3\sigma}{c_L h \rho_s \omega^2} \right) \left(\frac{\rho_s \omega \eta}{\rho_s \omega \eta + 2\rho c \sigma} \right) \quad (17)$$

From an examination of Eq. (16) it can be observed that for a properly designed enclosure the sound energy flows through gaps, openings, air intakes, and exhaust silencers, and structure-borne paths must be controlled so that their contributions to the sound radiation are small compared with the sound radiation from the walls. If these sound energy paths are fully controlled, then the sound energy dissipation is achieved by the total absorption area inside the enclosure $A_e = S_w \alpha_w + S_j \alpha_j$. Then if $TL_{wi} = TL$ and $S_w = S_e$, Eq. (16) simplifies to Eq. (9).

6 CLOSE-FITTING ENCLOSURES

If the noise source occupies no more than about one-third of the volume of a sealed enclosure, then the theory described by Eqs. (16) and (17) can be used. However, in many cases when machines are enclosed it is necessary to locate the enclosure walls close to the machine surfaces, so that the resulting air gap is small. Such enclosures are termed close-fitting enclosures. In such cases the sound field inside the enclosure is neither reverberant nor diffuse, and the theory discussed at the beginning of this chapter can be used to calculate a first approximation of the insertion loss of an enclosure.

Figure 5 Close-fitting enclosure attenuation in sound pressure level for different values of panel stiffness. The resonance frequency f_0 is increased by increasing stiffness.

There are several effects that occur with close-fitting enclosures. First, if the noise source has a low internal impedance, then in principle the close-fitting enclosure can “load” the source so that it produces less sound power. However, in most machinery noise problems, the internal impedance of the source is high enough to make this effect negligible. Second, and more importantly, reductions in the IL occur at certain frequencies (when the enclosure becomes “transparent”). These frequencies f_0 and f_{sw} are shown in Fig. 5. When an enclosure is close fitting, then to a first approximation the sound waves approach the enclosure walls at normal incidence instead of random incidence. When the air gap is small, then a resonant condition at frequency f_0 occurs where the enclosure wall mass is opposed by the wall and air gap stiffness. This resonance frequency can be increased by increasing the stiffness, as seen in Fig. 5. In addition, standing-wave resonances can occur in the air gap at frequencies f_{sw} . These resonances can be suppressed by the placement of sound-absorbing material in the air gap.^{11,12}

Jackson has produced simple theoretical models for close-fitting enclosures that assume a uniform air

Figure 6 Simplified one-dimensional model for a close-fitting enclosure.

gap.^{11,12} He modeled the source enclosure problem in terms of two parallel infinite panels separated by an air gap, as shown in Fig. 6. One panel is assumed to be vibrating and to be the noise source, and the second panel is assumed to be an enclosure panel. Then, the enclosure performance is specified in terms of the relative vibration levels of the two panels. Later, Junger considered both the source panel and enclosure panel to be of finite area.¹³ He assumed that the source panel vibrates as a uniform piston and the enclosure panel vibrates as a simply supported plate excited by a uniform sound pressure field. Comparisons of the Jackson, Junger, and Ver models have been presented by Tweed and Tree.¹⁴

Fahy has presented details of an enclosure prediction model based upon a one-dimensional model similar to that of Jackson.¹⁵ It is assumed that the enclosure panel is a uniform, nonflexible partition of mass per unit area ρ_s , and it is mounted upon viscously damped, elastic suspensions, having stiffness and damping coefficients

per unit area s and r , respectively. The insertion loss of the enclosure in this one-dimensional case is

$$IL = 10 \log \left\{ \left[\cos k\ell - \frac{(\omega\rho_s - s/\omega) \sin k\ell}{\rho c} \right]^2 + \sin^2 k\ell \left(1 + \frac{r}{\rho c} \right)^2 \right\} \quad (18)$$

where $k = \omega/c$ is the wavenumber, and ℓ is the separation distance between the source and enclosure panel.

From an examination of Eq. (18) it is clear that the insertion loss will be zero at frequencies when the cavity width ℓ is equal to an integer number of half-wavelengths and the panel enclosure velocity equals the source surface velocity. The insertion loss will also have a minimum value at the frequency ω_0 ¹⁵

$$\omega_0^2 \approx \frac{\rho c^2}{\rho_s \ell} + \frac{s}{\rho_s} \quad (19)$$

where $\omega_0 = 2\pi f_0$. Figure 7 shows a generalized theoretical insertion loss performance of a close-fitting enclosure, according to Eq. (18).

Other theoretical models to predict the acoustical performance of close-fitting enclosures have been reported in the literature.^{16,17} However, in practice, the real source panel exhibits forced vibrations in a number of modes and the air gap varies with real enclosures, and these simple theoretical models and some later ones can only be used to give some guidance of the insertion loss to be expected in practice. Finite element and boundary element approaches can be used to make insertion loss predictions for close-fitting enclosures with complicated geometries and for the intermediate frequency region.¹⁸

Figure 7 Theoretical close-fitting enclosure insertion loss performance.

Figure 8 Partial enclosure.

7 PARTIAL ENCLOSURES

When easy and continuous access to parts of a machine is necessary or the working process of the machinery or the safety or maintenance requirements do not allow a full enclosure, a partial enclosure is usually used to reduce the radiated noise.¹⁹ Figure 8 shows an example of a partial enclosure used in machinery noise control. The noise reduction produced by a partial enclosure will depend upon the particular geometry. Most of the time, the available attenuation will be limited by diffractive scattering and mechanical connections between the partial enclosure and the vibrating machine. It is recommended that partial enclosures be fully lined with sound absorption material. As a general rule, the enclosure walls of a partial enclosure should have a transmission loss of at least 20 dB. The maximum sound power reduction that can be achieved for such an enclosure is about 10 dB. However, in some cases, the noise levels radiated may be reduced more. Table 3 shows the effectiveness of partial enclosures, where the values are based on the assumption that the noise source radiates uniformly in all directions and that the partial enclosure that surrounds the source is fully lined with sound-absorptive material.²⁰

8 PRACTICAL DETAILS

Most equations presented in this chapter will give good estimates for the actual performance of an enclosure. However, some guidelines should be followed in practice to avoid degradation of the effectiveness of

an enclosure. In addition, when designing an enclosure, care should be taken so that production costs and time, operational cost-effectiveness, and the efficiency of operation of the machine or equipment being enclosed are not adversely affected.

Most enclosures will require some form of ventilation through openings. Such necessary permanent openings must be treated with some form of silencing to avoid substantially degrading the performance of the enclosure. For a good design, it is required that the acoustical performance of access silencing will match the performance of the enclosure walls. The usual techniques employed to control the sound propagation in ducts can be used for the design of silencers (see Chapter 112).

When ventilation for heat removal is required but the heat load is not large, then natural ventilation with silenced air inlets low down close to the floor and silenced outlets at a greater height, well above the floor, will be adequate. If forced ventilation is needed to avoid excessive heat build up in the enclosure, then the approximate amount of airflow needed can be determined by⁴

$$\rho C_p V = \frac{H}{\Delta T} \quad (20)$$

where V is the volume flow rate of the cooling air required (m^3/s), H is the heat input to the enclosure (W), ΔT is the temperature differential between the external ambient and the maximum permissible internal temperature of the enclosure ($^{\circ}\text{C}$), ρ is the air density (kg/m^3), and C_p is the specific heat of the air ($\text{m}^2\text{C}^{-1}/\text{s}^2$). When high-volume flow rates of air are required, the noise output of the fan that provides the forced ventilation should be considered very carefully, since this noise source can degrade the performance of the enclosure. In general, large slowly rotating fans are always preferred to small high-speed fans since fan noise increases with the fifth power of the blade tip speed.

The effectiveness of an enclosure can be very much reduced by the presence of leaks (air gaps). These usually occur around removable panels or where ducts or pipes enter an enclosure to provide electrical and cooling air services and the like. If holes or leaks occur in the enclosure walls (e.g., cracks around doors or around the base of a cover) and if the TL of the holes is assumed to be 0 dB (as is customary), then the reduction in insertion loss as a function of the TL of the enclosure walls, with the leak ratio factor β as the parameter is given by Fig. 9.² The leak ratio factor β is defined as the ratio of the total face area of the leaks and gaps to the surface area (one side) of the enclosure walls. If the penetrations in the enclosure walls are lined with absorbing materials as shown in Fig. 10, then the degradation in the enclosure IL is much less significant. Results from both a statistical energy model and experimental work for a steel box, representing a cabin enclosure, are presented in Figs. 11 and 12.⁷ Here the attenuation is defined as the difference in space-averaged sound pressure levels

Table 3 Effectiveness of a Partial Enclosure

outside and inside the enclosure. It can be observed how a circular aperture in one panel affects the

attenuation in the middle- and high-frequency range. Some studies indicate that leaks not only degrade the noise reduction but also can introduce resonances when the leak ratio factor is not very large.²¹

It is necessary to provide sufficient vibration isolation to reduce the radiation of noise from the surface on which the machinery is mounted, particularly if low-frequency noise is the main problem. Therefore, it is advisable to mount the machine and/or the enclosure itself on vibration isolators that reduce the transmission of energy to the floor slab. In doing so, control of both the airborne and the structure-borne sound transmission paths between the source and receiver will be provided. Great care is necessary to ensure that the machine will be stable and its operation will not be affected adversely. Insertion of flexible (resilient) connectors between the machine and conduit, cables, piping, or ductwork connected to it must be provided to act as vibration breaks.

In addition, proper breaking of any paths that permit noise to "leak" through openings in the enclosure must be provided. Then all joints, seams, and penetrations of enclosures should be sealed using a procedure such as packing the leaks with mineral wool, which are

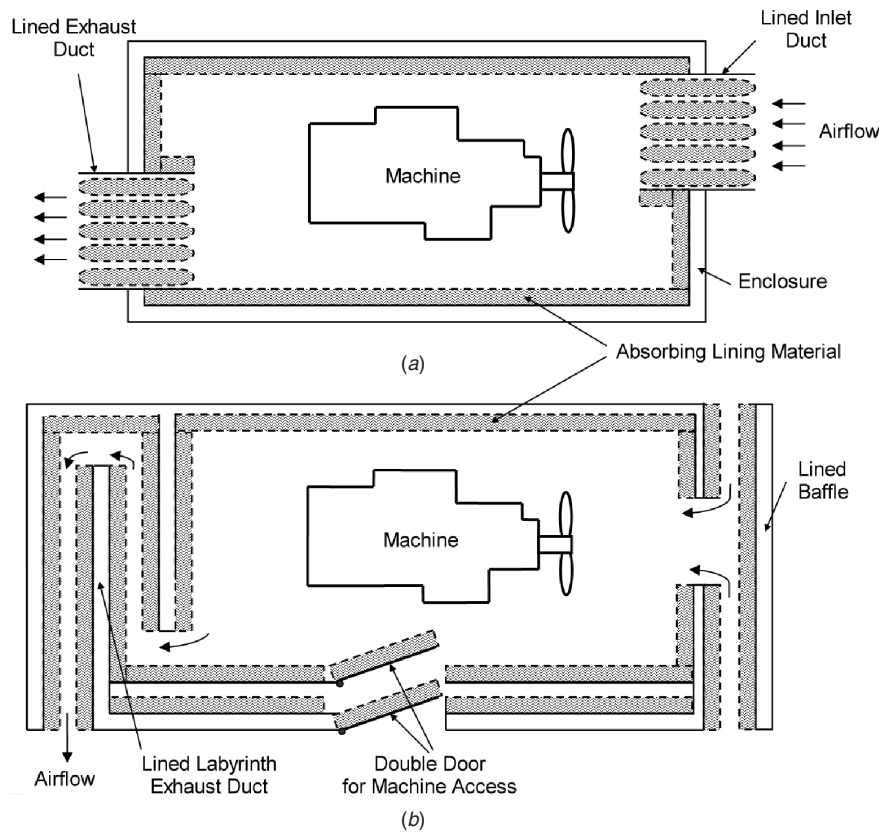

Figure 10 Enclosures with penetrations (for cooling) lined with absorbing materials: (a) lined ducts and (b) lined baffles with double-door access provided to interior of machine.

closed by cover plates and mastic sealant.⁴ Figure 13 shows the difference in experimental results between the attenuation of an idealized cab enclosure with the leaks between panels unsealed and sealed with clay.²²

Any access doors to the enclosure must be fitted tightly and gasketed. Locking handles should be

Figure 13 Experimentally measured attenuation of a cabin model enclosure: —, joints sealed and - - - , joints unsealed.

provided that draw all such doors tightly to the gasketed surfaces so as to provide airtight seals. Inspection windows should be double glazed and the glass thicknesses and pane separations should be chosen carefully to avoid degradation by structural/air gap resonances. Placing porous absorbing material in the reveals between the two frames supporting the glass panes can improve the transmission loss of a double-glazed inspection window. Figure 14 shows an enclosure in which some basic noise control techniques have been applied. Information about cost, construction details, and performance of several enclosures can be found in the manufacturers' literature and in some books.²³

1 INTRODUCTION

Sound-absorbing materials absorb most of the sound energy striking them and reflect very little. Therefore, sound-absorbing materials have been found to be very useful in the control of noise. They are used in a variety of locations: close to sources of noise (e.g., close to sources in electric motors), in various paths, (e.g., above barriers), and sometimes close to a receiver (e.g., inside earmuffs).

Although all materials do absorb some incident sound, the term *acoustical material* has been primarily applied to those materials that have been produced for the specific purpose of providing high values of sound absorption. The major uses of acoustical materials are almost invariably found to include the reduction of reverberant sound pressure levels and, consequently, the reduction of reverberation time in enclosures (rooms).

Since about 1965, the use and variety of available specialized acoustical materials has greatly increased. This has been due mainly to both increased technology and public awareness and concern about noise in everyday life. In turn, this has led many public bodies and commercial public service operations to realize the benefits of providing good acoustical conditions for their clients. The architect and acoustical engineer now have a wide choice of sound-absorbing materials that not only provide the desired acoustical properties but also offer an extremely wide variety of colors, shapes, sizes, light reflectivities, fire ratings, and methods of attachment. In addition to these qualities, users should consider the costs of purchase, installation, and upkeep.

2 SOUND ABSORPTION COEFFICIENT

When sound waves strike a boundary separating two media, some of the incident energy is reflected from the surface and the remaining energy is transmitted into the second medium. Some of this energy is eventually converted by various processes into heat energy and is said to have been absorbed by that medium. The fraction of the incident energy absorbed is termed the absorption coefficient $\alpha(f)$, which is a function of

frequency and defined as

$$\alpha(f) = \frac{\text{sound intensity absorbed}}{\text{sound intensity incident}} \quad (1)$$

The absorption coefficient theoretically ranges from zero to unity. In practice, values of $\alpha > 1.0$ are sometimes measured. This anomaly is due to the measurement procedures adopted to measure large-scale building materials.

One sabin is defined as the sound absorption of one square metre of a perfectly absorbing surface, such as an open window. The sound absorption of a wall or some other surface is the area of the surface, in square metres, multiplied by the absorption coefficient.

3 NOISE REDUCTION COEFFICIENT

Another parameter often of interest in assessing the performance of an acoustical absorber is the single number known as the noise reduction coefficient (NRC). The NRC of a sound-absorbing material is given by the average of the measured absorption coefficients for the 250-, 500-, 1,000-, and 2,000-Hz octave bands rounded off to the nearest multiple of 0.05. This NRC value is often useful in the determination of the applicability of a material to a particular situation. However, where low or very high frequencies are involved, it is usually better to consider sound absorption coefficients instead of NRC data (see also Chapter 54).

4 ABSORBERS

A wide range of sound-absorbing materials exist that provide absorption properties dependent upon frequency, composition, thickness, surface finish, and method of mounting. They can be divided into several major classifications. Materials that have a high value of α are usually porous and fibrous. Fibrous materials include those made from natural or artificial fibers including glass fibers. Porous materials made from open-celled polyurethane are also widely used.

4.1 Porous Fibrous Sound Absorbers

Porous materials are characterized by the fact that the nature of their surfaces is such that sound energy is

able to enter the materials by a multitude of small holes or openings. They consist of a series of tunnel-like pores and openings formed by interstices in material fibers or by foamed products. (Usually, within limitations, the more open and connecting these passages are, the larger the values of the sound-absorbing efficiency of the material.) If, on the other hand, the pores and penetrations are small and not joined together, then the material becomes substantially less efficient as a sound absorber. Included in this broad category of porous absorbers are fibrous blankets, hair felt, wood-wool, acoustical plaster, a variety of spray-on products, and certain types of acoustical tiles.

When a porous material is exposed to incident sound waves, the air molecules at the surface of the material and within the pores of the material are forced to vibrate and in the process lose energy. This is caused by the conversion of sound energy into heat due to thermal and viscous losses of air molecules at the walls of the interior pores and tunnels in the sound-absorbing material. At low frequencies these changes are isothermal, while at high frequencies they are adiabatic. In fibrous materials, much of the energy can also be absorbed by scattering from the fibers and by the vibration caused in the individual fibers. The fibers of the material rub together under the influence of the sound waves and lose energy due to work done by the frictional forces. Figure 1 shows the two main mechanisms by which the sound is absorbed in materials. For this reason high values of absorption coefficient in excess of 0.95 can be observed. Depending upon how α is determined experimentally, values in excess of unity can also be measured just how this happens will be discussed later. The values of α observed are usually strongly dependent upon (a) frequency, (b) thickness,

Figure 1 Two main mechanisms believed to exist in sound-absorbing materials: (a) viscous losses in air channels and (b) mechanical friction caused by fibers rubbing together.

Figure 2 Typical absorption coefficient vs. octave band frequency characteristics for a 25-mm-thick fibrous absorbing material. Curve A is for the material laid directly on a rigid backing, while curve B shows the effect of introducing a 10-cm air gap.

and (c) method of mounting. These should always be considered in the choice of a particular material.

Figure 2 shows typical sound absorption characteristics for a blanket-type fibrous porous material placed (Fig. 2a) against a hard wall, and (Fig. 2b) with a 10-cm airspace between the material and the wall. In both cases the absorption properties are substantially better at high frequencies than low. When the same material is backed by an airspace, the low-frequency absorption is improved without significantly changing the high-frequency characteristics. Figure 3 shows the effect of increasing the thickness of the material on a solid backing. Again, increased low-frequency absorption is observed for increased thickness.

Figure 3 Sound absorption coefficient α and noise reduction coefficient (NRC) for typical fiberglass foamboard.

An additional effect to consider is that of surface treatment since most materials will become discolored or dirty after prolonged exposure for several years and may require cleaning or refinishing. Because the surface pores must be open to incident sound for the porous material to function, it is essential that they should not be blocked with paint or any other surface-coating treatment. The effects of brush painting porous materials are usually more severe than spray painting; however, the usual effect is to lower the absorption coefficient to about 50% of its unpainted value particularly at high frequencies. In addition, the absorption peak is shifted downward in frequency as observed by Price and Mulholland.¹ As more coats of paint are applied, the paint membrane becomes more dense and more pores are sealed, the result of which is to shift the absorption peak even lower in frequency and magnitude.

It is useful now to describe briefly the physical parameters used to account for the sound-absorbing and attenuating properties of porous materials. These include flow resistivity, porosity, volume coefficients of elasticity of both air and the skeleton, structural form factor (tortuosity), and specific acoustic impedance. These will now be described separately.

4.1.1 Flow Resistivity R This accounts for the resistance offered to airflow through the medium. It is defined in the metre-kilogram-second (mks) system as

$$R = \frac{\Delta p}{U} \frac{1}{t} \quad (2)$$

where R is the flow resistivity (mks rayls/m), Δp is the differential sound pressure created across a sample of thickness t , measured in the direction of airflow (N/m^2), U is the mean steady flow velocity (m/s), and t is the thickness of the porous material sample (m).

Typical values for porous fibrous materials vary from 4×10^3 to 4×10^4 mks rayls/m for a density range of 16 to 160 kg/m^3 . Generally speaking, if the flow resistivity R becomes very large, then most of the incident sound falling on the material will be reflected, while if R is too small, then the material will offer only very slight viscous losses to sound passing through it, and so it will provide only little sound absorption or attenuation. Although the absorption is proportional to thickness, it is generally found that for a given flow resistivity value R , the optimum thickness of material is approximately given by $t = 100/\sqrt{R}$.

4.1.2 Porosity ε The porosity of a porous material is defined as the ratio of the void space within the material to its total displacement volume as

$$\varepsilon = \frac{V_a}{V_m} \quad (3)$$

where V_a is the volume of air in the void space in the sample and V_m is the total volume of the sample. It has to be noticed that the void space is only that

accessible to sound waves. For a material composed of solid fibers the porosity can be estimated from

$$\varepsilon = 1 - \frac{M_s}{V_s \rho_F} \quad (4)$$

where M_s is the total mass of sample (kg), V_s is the total volume of sample (m^3), and ρ_F is the density of fibers (kg/m^3). Typical values of porosity for acceptable acoustical materials are greater than 0.85.

4.1.3 Volume Coefficient of Elasticity of Air K This is the bulk modulus of air defined from

$$\Delta p = -K \frac{\Delta V}{V} \quad (5)$$

where Δp is the change in pressure required to alter the volume V by an increment ΔV (N/m^2), ΔV is the incremental change in volume (m^3), and K is the volume coefficient of elasticity (N/m^2).

4.1.4 Volume Coefficient of Elasticity of the Skeleton Q This is defined in a similar way to the bulk modulus, which is the change in thickness of a sample sandwiched between two plates as the force applied on them is increased, that is,

$$\delta F = -Q \frac{\delta t}{t} S \quad (6)$$

where δF is the incremental force applied to the sample (N), δt is the incremental change in thickness of the sample (m), t is the original thickness (m), Q is the volume coefficient of elasticity of the skeleton (N/m^2), and S is the sample area (m^2).

4.1.5 Structural Form Factor k_s It is found that in addition to the flow resistance, the composition of the inner structure of the pores also affects the acoustical behavior of porous materials. This is because the orientation of the pores relative to the incident sound field has an effect on the sound propagation. This has been dealt with by Zwicker and Kosten² and treated as an effective increase in the density of the air in the void space of the material. Beranek³ reports that flexible blankets have structure factors between 1 and 1.2, while rigid tiles have values between 1 and 3. He also shows that for homogeneous materials made of fibers with interconnecting pores the relationship between the porosity ε and structure factor k_s is $k_s \approx 5.5 - 4.5\varepsilon$. In the technical literature it is possible to find the self-explanatory term *tortuosity* instead of structural form factor. For most fibrous materials the structural form factor is approximately unity.

4.1.6 Specific Acoustic Impedance z_0 This is defined as the ratio of the sound pressure p to particle velocity u at the surface of the material, for a sample of infinite depth, when plane sound waves strike the

surface at normal incidence. This is a complex quantity and it is defined mathematically as

$$z_0 = \frac{p}{u} = \rho c(r_n + jx_n) \quad (7)$$

where r_n is the normal specific acoustic resistance, x_n is the normal specific acoustic reactance, ρc is the characteristic impedance of air (415 mks rays), and $j = \sqrt{-1}$.

It is useful to look briefly at some of the interesting relationships that exist between the specific impedance and the absorption coefficient under certain circumstances. For example, if a porous material is composed so that $r_n \gg 1$ and $r_n \gg x_n$, the absorption coefficient α_θ for a sound wave striking a surface at angle θ to the normal is given by

$$\alpha_\theta = \frac{4r_n \cos \theta}{(1 + r_n \cos \theta)^2} \quad (8)$$

Furthermore, for a diffuse sound field, the random incidence absorption coefficient α is given by⁴

$$\alpha = \frac{8}{r_n} \left[1 + \frac{1}{1 + r_n} - \frac{2}{r_n} \ln(1 + r_n) \right] \quad (9)$$

If $r_n > 100$ (materials with small absorption coefficients), this equation can be substantially simplified to $\alpha = 8/r_n$.

The use of the complex acoustic impedance, rather than absorption coefficient, allows a much more rigorous treatment of low-frequency room reverberation time analysis. Although often considerably more complex than the classical theory, this approach does predict more accurate values of reverberation times in rooms containing uneven distribution of absorption material, even if either pair of opposite walls are highly absorbing or if opposite walls are composed of one very soft and one very hard wall.⁴

Beranek shows^{3,5} that the specific acoustic impedance of a rigid tile can be written in terms of the previously defined fundamental parameters as

$$z_0 = \left[\rho \frac{k_s K}{\varepsilon} \left(1 - j \frac{R}{\rho k_s \omega} \right) \right]^{1/2} \quad (10)$$

where ρ is the density of air (kg/m^3) and ω is the angular frequency (rads/).

It can therefore be seen from Eqs. (7), (9), and (10) that the absorption coefficient is proportional to the porosity and flow resistance of the material (provided $r_n > 100$ and $r_n \gg x_n$), and is inversely proportional to the density and structure factor. For soft blankets, the expressions for the acoustic impedance become very much more complex and the reader is directed to Refs. 2, 3, and 5 for a much more complete analysis.

The basic theory used to model the sound propagation within porous absorbents assumes that the

absorber frame is rigid and the waves only propagate in the air pores. This is the typical case when the porous absorber is attached to a wall or resting on a floor that constrains the motion of the absorber frame. Neglecting the effect of the structural form factor, it can be shown that plane waves in such a material are only possible if the wavenumber is given by⁶

$$k_p = k \sqrt{1 + j \frac{R\varepsilon}{\omega\rho}} \quad (11)$$

where k is the free-field wavenumber in air (m^{-1}) and ρ is the density of air (kg/m^3). In addition, the wave impedance of plane waves is

$$z_0 = \frac{\rho c}{\varepsilon} \frac{k_p}{k} \quad (12)$$

In another method of analysis a fibrous medium is considered to be composed of an array of parallel elastic fibers in which a scattering of incident sound waves takes place resulting in conversion to viscous and thermal waves by scattering at the boundaries. This approach was first used by Rayleigh⁷ and has since been refined by several researchers. Attenborough and Walker included effects of multiple scattering in the theory⁸ that is able to give good predictions of the impedance of porous fibrous materials. However, even more refined phenomenological models have been presented in recent years.⁹

On the other hand, very useful empirical expressions to predict both the propagation wavenumber and characteristic impedance of a porous absorbent have been developed by Delany and Bazley.¹⁰ The expressions as functions of frequency f and flow resistivity R are

$$k_p = k(1 + 0.0978X^{-0.7} - j0.189X^{-0.595}) \quad (13)$$

and

$$z_0 = \rho c(1 + 0.0571X^{-0.754} - j0.087X^{-0.732}) \quad (14)$$

where $X = \rho f/R$. Equations (13) and (14) are valid for $0.01 < X < 1.0$, $10^3 \leq R \leq 5 \times 10^4$, and $\varepsilon \approx 1$.

Additional improvements to the Delany and Bazley empirical model have been presented by other authors.^{11,12} If the frame of the sound absorber is not constrained (elastic-framed material), a more complete "poroelastic" model of sound propagation can be developed using the Biot theory.¹³ In addition, both guidelines and charts for designing absorptive devices using several layers of absorbing materials have been presented.^{14,15}

4.2. Panel or Membrane Absorbers

When a sound source is turned on in a room, a complex pattern of room modes is set up, each having its own

characteristic frequency. These room modes are able, in turn, to couple acoustically with structures in the room, or even the boundaries of the room, in such a way that acoustic power can be fed from the room modes to other structural modes in, for example, a panel hung in the room.

A simply supported plate or panel can only vibrate at certain allowed natural frequencies $f_{m,n}$ and these are given by

$$f_{m,n} = 0.453c_L h \left[\left(\frac{m}{l_x} \right)^2 + \left(\frac{n}{l_y} \right)^2 \right] \quad (15)$$

where $f_{m,n}$ is the characteristic modal frequency, m and n are integers (1, 2, 3, ...), c_L is the longitudinal wave speed in the plate material (m/s), h is the thickness of the plate (m), and l_x and l_y are the dimensions of the plate (m).

If $m = n = 1$, then this gives the first allowable mode of vibration along with its fundamental natural frequency $f_{1,1}$. The above equation is valid only for plates with simply supported edges. For a plate with clamped edges the fundamental mode occurs at approximately twice the frequency calculated from Eq. (15). Thus a room mode, at or close to the fundamental frequency of a plate hung in the room, will excite the plate fundamental mode. In this way the plate will be in a resonant condition and therefore have a relatively large vibration amplitude. In turn, this will cause the plate to dissipate some of its energy through damping and radiation. Therefore, the plate can act as an absorber having maximum absorption characteristics at its fundamental frequency (and higher order modes), which will depend upon the geometry of the plate and its damping characteristics. In all practical cases this effect takes place at low frequencies, usually in the range 40 to 300 Hz. Particular care has to be taken, therefore, that any panels that may be hung in a room to improve reflection or diffusion are not designed in such a manner that they act as good low-frequency absorbers and have a detrimental effect on the acoustics of the space.

If a panel is hung in front of a hard wall at a small distance from it, then the airspace acts as a compliant element (spring) giving rise to a resonant system comprised of the panel's lumped mass and the air compliance. The resonance frequency f_r (Hz) of the system is

$$f_r \approx \frac{59.5}{\sqrt{Md}} \quad (16)$$

where M is the mass surface density (kg/m^2), and d is the airspace depth (m).

Hence, a thin panel of 4 kg/m^2 weight placed a distance of 25 mm from a rigid wall will have a resonance frequency of 188 Hz. As in the case of a simply supported panel, a spaced panel absorbs energy through its internal viscous damping.^{16,17} Since its vibration amplitude is largest at resonance, its sound-absorption is maximum at this frequency. Usually this

absorption can be both further increased in magnitude and extended in its effective frequency range (i.e., giving a broader resonance peak) by including a porous sound-absorbing material, such as a fiberglass blanket, in the airspace contained by the panel. This effectively introduces damping into the resonant system.

Figure 4 shows the effect of introducing a 25-mm-thick fibrous blanket into the 45-mm airspace contained by a 3-mm plywood sheet. The change is quite significant at low frequencies in the region of the resonance peak where both the magnitude and width of the peak are increased. On the other hand, there is little effect at high frequencies.

Membrane absorbers are one of the most common bass absorbers used in small rooms. In addition, their nonperforated surfaces are durable and can be painted with no effect on their acoustical properties. It is important that this type of sound absorber be recognized as such in the design of an auditorium. Failure to do so, or to underestimate its effect, will lead to excessive low-frequency absorption, and the room will have a relatively short reverberation time. The room will then be considered to be acoustically unbalanced and will lack warmth. Typical panel absorbers found in auditoriums include gypsum board partitions, wood paneling, windows, wood floors, suspended ceilings, ceiling reflectors, and wood platforms.

Porous materials also possess better low-frequency absorption properties when spaced away from their solid backing (see Fig. 2) and behave in a manner similar to the above solid panel absorbers. When the airspace equals one-quarter wavelength, maximum absorption will occur, while when this distance is a one-half wavelength, minimum absorption will be realized. This is due to the fact that maximum air particle velocity occurs at one-quarter wavelength from

Figure 4 Effect on the sound absorption coefficient α of placing a 25-mm-thick sound-absorptive blanket in the airspace (45-mm deep) behind a flexible 3-mm plywood panel.

the wall and hence provides the maximum airflow through the porous material. This, in turn, provides increased absorption at that frequency. Such an effect can be useful in considering the performance of curtains or drapes hanging in an auditorium. A similar effect is observed for hanging or suspended acoustical ceilings.¹⁸

To achieve well-balanced low-frequency absorption, a selection of different size and thickness spaced panels can be used and indeed have been used successfully in many auditoriums. Combinations of resonant panels have also been suggested.¹⁹

4.3 Helmholtz Resonator Absorbers

A Helmholtz resonator, in its simplest form, consists of an acoustical cavity contained by rigid walls and connected to the exterior by a small opening called the neck, as shown in Fig. 5. Incident sound causes air molecules to vibrate back and forth in the neck section of the resonator like a vibrating mass while the air in the cavity behaves like a spring. As shown in the previous section, such an acoustical mass-spring system has a particular frequency at which it becomes resonant. At this frequency, energy losses in the system due to frictional and viscous forces acting on the air molecules in and close to the neck become maximum, and so the absorption characteristics also peak at that frequency. Usually there will be only a very small amount of damping in the system, and hence the resonance peak is usually very sharp and narrow, falling off very quickly on each side of the resonance frequency. This effect can be observed easily if we blow across the top of the neck of a bottle, we hear a pure tone developed rather than a broad resonance.

If the neck is circular in cross section and if we neglect boundary layer effects, the undamped resonance frequency f_r is given by

$$f_r = \frac{c}{2\pi} \sqrt{\frac{S}{(L + 1.7r)V}} \quad (17)$$

where S is the area of the neck (m^2), L is the length of neck (m), r is the radius of neck (m), V is the cavity volume (m^3), and c is the speed of sound (m/s). The factor $(L + 1.7r)$ in Eq. (17) gives the effective length

Figure 5 A Helmholtz resonator consists of a neck of length L and cross-sectional area S , and backed by a closed volume V .

of the baffled neck. The factor $1.7r$ is sometimes called the *end correction*.

Although Helmholtz-type resonators can be built to be effective at any frequency, their size is such that they are used mainly for low frequencies in the region 20 to 400 Hz. Because of their sharp resonance peaks, undamped resonator absorbers have particularly selective absorption characteristics. Therefore, they are used primarily in situations where a particularly long reverberation time is observed at one frequency. This frequency may correspond to a well-excited low-frequency room mode, and an undamped resonator absorber may be used to reduce this effect without changing the reverberation at other, even nearby, frequencies. They are also used in noise control applications where good low-frequency sound absorption is required at a particular frequency. In this respect special Helmholtz resonators, constructed from hollow concrete blocks with an aperture or slit in their faces, are used in transformer rooms and electrical power stations to absorb the strong 120-Hz noise produced therein.

This concept is well known and such a resonator was used hundreds of years ago in some churches built in Europe. Some damping may be introduced into such resonators by adding porous material either in the neck region or to a lesser extent in the cavity. The effect of increased damping is to decrease the absorption value at resonance but considerably to broaden the absorption curve over a wider frequency range. Figure 6 shows measured absorption coefficients for slotted concrete blocks filled with porous material. It can be seen that they offer especially good low-frequency absorption characteristics. In addition, they can be faced with a thin blanket of porous material and covered with perforated metal sheeting, as shown in Fig. 7, to improve their high-frequency absorption with only little effect on their low-frequency performance.

Figure 6 Sound absorption coefficient vs. frequency for a slotted 20-cm concrete block filled with an incombustible fibrous material.

Figure 7 Slotted concrete blocks faced with fiberglass and covered with a perforated metal provide good low- and high-frequency absorption characteristics.

It is useful to note that there is a limit to the absorption any given undamped resonator of this type can provide. According to Zwicker and Kosten² the maximum absorption possible, A_{\max} sabins, is given by

$$A_{\max} = 1.717 \left(\frac{c}{f_r} \right)^2 \quad (18)$$

where c is the speed of sound (m/s) and f_r is the resonance frequency (Hz). Therefore, if $f_r = 150$ Hz, for example, then we cannot expect to realize more than $A_{\max} = 8.5$ sabins per unit. Equation (18) also shows that as the resonance frequency becomes lower, more absorption can be obtained from the resonator.

In certain circumstances, the performance of a Helmholtz-type resonator can be drastically influenced by the effect of its surrounding space. This is particularly found in the case for such resonators mounted in a highly absorbing plane, when interference can take place between the sound radiated from the resonator and reflected from the absorbing plane. In such circumstances special care has to be taken.

4.3.1 Perforated Panel Absorbers As described above, single Helmholtz resonators have very selective absorption characteristics and are often expensive to construct and install. In addition, their main application lies at low frequencies. Perforated panels offer an extension to the single resonator absorber and provide a number of functional and economic advantages.

When spaced away from a solid backing, a perforated panel is effectively made up of a large number of individual Helmholtz resonators, each consisting of a “neck,” constituted by the perforation of the panel, and a shared air volume formed by the

total volume of air enclosed by the panel and its backing. The perforations are usually holes or slots and, as with the single resonator, porous material may be included in the airspace to introduce damping into the system. Perforated panels are mechanically durable and can be designed to provide good broadband sound absorption. The addition of a porous blanket into the airspace tends to lower the magnitude of the absorption maximum but, depending on the resistance of the material, generally broadens the effective range of the absorber.²⁰ At low frequencies the perforations become somewhat acoustically transparent because of diffraction, and so the absorbing properties of the porous blanket remain almost unchanged. This is not so at high frequencies at which a reduction in the porous material absorption characteristics is observed.

The resonance frequency f_r for a panel perforated with holes and spaced from a rigid wall may be calculated from

$$f_r = \frac{c}{2\pi} \sqrt{\frac{P}{Dh'}} \quad (19)$$

where c is the speed of sound (m/s), D is the distance from wall (m), h' is the thickness of the panel with the end correction (m), r is the radius of hole or perforation (m), and P is the open area ratio (or perforation ratio). For a panel made up of holes of radius r metres and spaced s metres apart, the open area ratio P is given by $\pi(r/s)^2$ (see Fig. 8).

A full expression for h' in Eq. (19) that takes into account the boundary layer effect is given by²¹

$$h' = h + 2\delta r + \left[\frac{8\nu}{\omega} \left(1 + \frac{h}{2r} \right) \right]^{1/2} \quad (20)$$

Figure 8 Geometry for a typical perforated panel absorber.

where h is the thickness of panel (m), ω is the angular frequency (rad/s), ν is the kinematic viscosity of air ($15 \times 10^{-6} \text{ m}^2/\text{s}$), and δ is the end correction factor. For panel hole sizes not too small we can write $h' \approx h + 2\delta r$. To a first approximation the end correction factor can be assumed to be 0.85, as we did in the previous section for a single hole. However, more accurate results that include the effects of the mutual interaction between the perforations have been predicted. Table 1 presents some of these results.

We can see that the resonance frequency increases with the open area ratio (i.e., the number of holes per unit area) and is inversely proportional to the thickness of the panel and its distance from the solid backing.

Example 1 A perforated panel with a 10% open area ($P = 0.10$) and thickness 6 mm is installed 15 cm in front of a solid wall. Assuming that the holes are not too small and if we neglect the end effect and put $h' = h + 2\delta r = 6 \text{ mm}$ and $D = 15 \text{ cm}$, then the resonance frequency $f_r = 560 \text{ Hz}$. If the percentage open area is only 1% ($P = 0.01$), then in the same situation, $f_r = 177 \text{ Hz}$.

In practical situations, air spaces up to 30 cm can be used with open areas ranging from 1 to 30% and thicknesses from 3 to 25 mm. These particular restrictions would allow a resonance frequency range of 60 to 4600 Hz. Many perforated panels and boards

are commercially available and are readily used for perforated absorbers. These include: hardboards, plastic sheets, wood and plywood panels, and a variety of plane and corrugated metal facings. Some perforated sheets are available that consist of a number of different size perforations on one sheet. This can be useful to give broader absorption characteristics.

Recently, microperforated panels have been developed, which means that the diameter of the perforations is very small (less than a millimetre). In this case, the diameter is comparable to the thickness of the boundary layer, resulting in high viscous losses as air passes through the perforations and, consequently, achieving absorption without using a porous material.^{22–24} Some commercial microperforated panels take advantage of this fact, allowing the construction of a transparent absorbent device similar to a double glazing unit. However, obtaining broadband sound absorption using microperforated panels is difficult and requires the use of multiple layers, increasing the depth and cost of the device.

Another technique commonly used to achieve broader absorption characteristics is to use a variable, often wedge-shaped, airspace behind the perforated panel,²⁵ as shown in Fig. 9. One of the commercial types of perforated absorber has been referenced in the literature as the “Kulihat.”²⁶ This is a conical absorber consisting of two or three perforated aluminum sectors held together by steel clips. The interior of the Kulihat is lined with mineral wool.

It is common practice to install a thin (1 to 2 mil) plastic sheet behind the perforated panel to cover and protect the porous absorbing material, as shown in Fig. 10. As long as this sheet is thin, its effect is usually only observed at high frequencies where the

Figure 9 Variable airspace perforated panels give broader absorption characteristics than those with a constant air depth. Here the panel is 16 mm thick and has holes of 9.5 mm in diameter spaced 3.5 cm on center.

Table 1 Different Formulas for the End Correction Factor

δ	Notes
0.85	Single hole in a baffle
$0.8(1 - 1.4\sqrt{P})$	For $P < 0.16$
$0.8(1 - 1.47\sqrt{P} + 0.47\sqrt{P^3})$	Includes $P = 1$
$0.85(1 - 1.25\sqrt{P})$	Square apertures; for $P < 0.16$
$-\ln[\sin(\pi P/2)]/\pi$	Slotted plate; in Eq. (20) $\nu = 0$ and $r = \text{width of slots}$

effective absorption can be reduced by approximately 10% of its value with no covering sheet present.

4.3.2 Slit Absorbers Another type of perforated resonator is the slit or slat absorber. These are made up of wooden battens fixed fairly close together and spaced at some distance from a solid backing. Porous material is usually introduced into the air cavity (see Fig. 11). This type of resonator is fairly popular architecturally since it can be constructed in many ways, offering a wide range of design alternatives. Equation (19) does not hold for slat absorbers since the perforations are very long. For a detailed discussion of the properties of such absorbers, the reader is advised to consult Refs. 27 and 28. The principle of the slit resonator is, however, the same as for a general Helmholtz resonator. The resonance frequency f_r (Hz) is given by the solution to the following equation:

$$f_r = \frac{c}{2\pi} \sqrt{\frac{a}{S}} \left\{ d + \frac{2a}{\pi} \left[1.12 + \ln \left(\frac{c}{\pi a f_r} \right) \right] \right\}^{-1/2} \quad (21)$$

where c is the speed of sound (m/s), a is the slit width (m), d is the slit depth (m), and S is the cross-sectional area (m²) of space behind slats formed by each slat (i.e., slat width $W \times$ air space D).

A typical acoustical design procedure would be to choose a resonance frequency f_r and a slat of width W and thickness d and then determine the required value of air space from $S = W \times D$ for a chosen value of slit width a .

Example 2 Let us suppose that we want $f_r = 200$ Hz and that the resonator should be constructed of slats measuring 25×84 mm. Therefore, we have $W = 84$ mm and $d = 25$ mm. Since the slit width should be approximately 10 to 20% the width of the slat, let us try a slat spacing (i.e., slit width) of 8 mm. Then, all the known values in Eq. (21) are $f_r = 200$ Hz, $W = 0.084$ m, $d = 0.025$ m, $a = 0.008$ m, and $c = 334$ m/s. Equation (21) can be rewritten by multiplying and dividing both sides of the equation by \sqrt{S} and f_r , respectively. Then, S can be obtained by squaring both sides of the resulting equation. Replacing the known

Figure 11 Slat type of resonator absorber (normally the mineral wool is placed immediately behind the slots).

values gives $S = 0.01\text{m}^2$ and since $W = 0.084$ m, we require $D = 0.13$ m.

We see, therefore, that for the above example of a slit resonator, an air space of 13 cm is required to provide a resonance frequency of 200 Hz. If the calculation is repeated for a 100-Hz resonance frequency, it is found that an air space of some 48 cm is required.

Figure 12 shows a comparison of typical sound absorption curves for most of the absorbers discussed above.

4.4 Suspended Absorbers

This class of sound absorbers is known by several names including *suspended absorbers*, *functional absorbers*, and *space absorbers*. They generally refer to sound-absorbing objects and surfaces that can be easily suspended, either as single units or as a group of single units within a room. They are particularly useful in rooms in which it is difficult to find enough surface area to attach conventional acoustical-absorbing materials either through simple lack of available space or interference from other objects or mechanical services such as ducts and pipes, in the ceiling space (see Fig. 13). It is relatively easy and inexpensive to install them, without interference to existing equipment. For this reason they are often used in noisy industrial installations such as assembly rooms or machine shops.

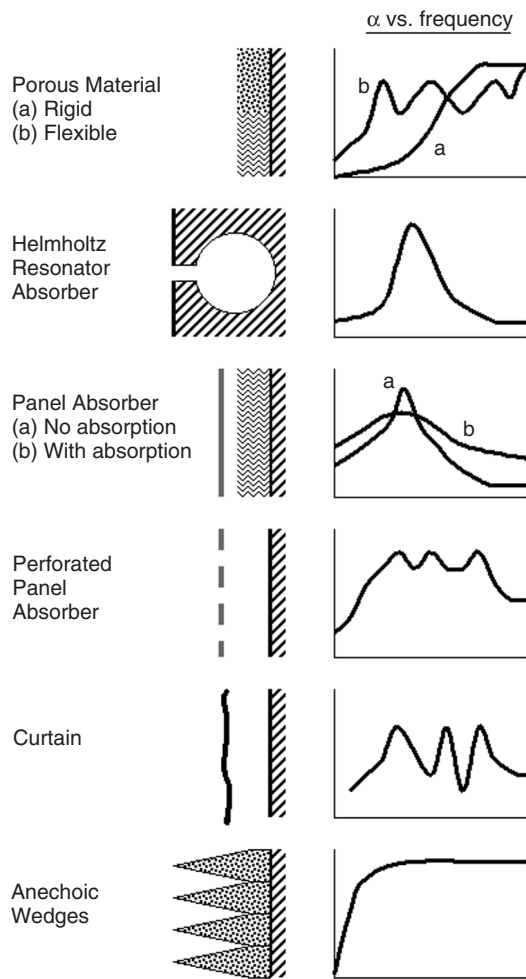

Figure 12 Comparison of acoustical behavior for typical sound absorbers.

Functional absorbers are usually made from highly absorbing materials in the form of a variety of three-dimensional shapes, such as spheres, cones, double cones, cubes, and panels. These are usually filled with a porous absorbing material. Since sound waves fall on all their surfaces and because of diffraction, they are able to yield high values of effective absorption coefficients. It is, however, more usual to describe their absorption characteristics in terms of their total absorption in sabins per unit, as a function of octave band frequencies, rather than to assign an absorption coefficient to their surfaces. One also finds that when a group of functional absorbers are installed, the total absorption realized from the group depends upon the spacing between the individual units to a certain extent. Once a certain optimum spacing has been reached the effective absorption per unit does not increase.^{29,30}

4.5 Acoustical Spray-on Materials

These consist of a range of materials formed from mineral or synthetic organic fibers mixed with a binding agent to hold the fibrous content together in a porous manner and also to act as an adhesive. During the spraying application, the fibrous material is mixed with a binding agent and water to produce a soft lightweight material of coarse surface texture with high sound-absorbing characteristics. Due to the nature of the binding agent used, the material may be easily applied directly to a wide number of surface types including wood, concrete, metal lath, steel, and galvanized metal. When sprayed onto a solid backing, this type of spray-on material usually exhibits good mid- and high-frequency absorption and when applied to, for example, metal lath with an airspace behind it, the material then also exhibits good low-frequency absorption. As would be expected from previous discussions of porous absorbers (in Section 4.1), the absorption values increase with greater depth of application, especially at low frequencies. Spray-on depths of up to 5 cm are fairly common.

Figure 13 Sound-absorbing material placed on the walls and under the roof and suspended as panels in a factory building.

The absorption characteristics of such materials are very much dependent upon the amount and type of binding agent used and the way it is mixed during the spray-on process. If too much binder is used, then the material becomes too hard and therefore a poor absorber, while on the other hand, if too little binder is employed, the material will be prone to disintegration; and, since it will have a very low flow resistance, it will also not be a good absorber.¹⁸ Some products use two binders. One is impregnated into the fibrous material during manufacture, while the other is in liquid form and included during application. The fibrous material (containing its own adhesive) and the liquid adhesive are applied simultaneously to the surface using a special nozzle. The material is particularly resistant to disintegration or shrinkage and, furthermore, is fire resistant and possesses excellent thermal insulation properties.

If visually acceptable, spray-on materials of this type can be successfully used as good broadband absorbing materials in a variety of architectural spaces including schools, gymnasiums, auditoriums, shopping centers, pools, sports stadiums, and in a variety of industrial applications such as machine shops and power plants. Disadvantages generally include the difficulty to clean and redecorate the material, although some manufacturers claim that their product can be spray painted without loss of acoustical performance. Such claims should be supported by data before proceeding to paint such a surface.

4.6 Acoustical Plaster

This term has been applied to a number of combinations of vermiculite and binder agents such as gypsum or lime. They are usually applied either to a plaster base or to concrete and must have a solid backing. Because of this, acoustical plasters have poor low-frequency absorption characteristics (also due to the thickness of application, which rarely exceeds 13 mm). This can be slightly improved by application to metal lath. The material may be applied by a hand trowel or by machine. However, the latter tends to compact the material and give lower absorption characteristics. The surface of acoustical plasters can be sprayed with water-thinned emulsion paint without any significant loss of absorption, although brushed oil-based paints should never be used. Figure 14 shows typical sound absorption characteristics for a 13-mm-thick hand trowel applied acoustical plaster taken from a variety of published manufacturer's data.¹⁸

5 MEASUREMENT OF ABSORPTION COEFFICIENTS

Although some approximate values for absorption coefficients and resonance frequency characteristics can be estimated from the geometry, flow resistance, porosity, and other physical factors, it is clearly necessary to have actual measured values of absorption coefficients for a variety of materials and different constructions. There are two standardized methods to measure the sound absorption coefficient: using a

Figure 14 Sound absorption coefficient α of a 13-mm-thick acoustical plaster.

reverberant room and using an impedance tube. These methods will be described in the following sections.

5.1 Using Reverberant Rooms

Since the reverberation time of a room depends upon the absorption present within it, this gives us a method to measure the absorption coefficient of a chosen material by observing the change in the reverberation time of the room caused by the introduction of the specimen. This method is particularly useful since large specimens of absorbing material can be measured that can be built and mounted in the same manner as they will be used in a real building. Therefore, these measurements should be more representative than those made on small samples.

If the reverberation time of a large, empty, and highly reverberant room is T_1 seconds and the sound field is completely diffuse, introduction of a sample of absorbing material of surface S will change the reverberation time to T_2 seconds at the same frequency. If we assume that the room temperature and humidity have remained unchanged throughout the measurements, the change in the total effective absorption ΔA (difference between the total absorption area of room and sample and total absorption area with empty walls) is given by

$$\Delta A = \frac{55.3V}{c} \left(\frac{1}{T_2} - \frac{1}{T_1} \right) \quad (22)$$

where V is the room volume (m^3) and c is the speed of sound (m/s).

Since that change in total absorption area is due to the sample of area S and effective absorption coefficient $\bar{\alpha}$ covering a wall surface, the effective absorption coefficient of the sample can be estimated

by the following equation:

$$\bar{\alpha} = \frac{55.3V}{Sc} \left(\frac{1}{T_2} - \frac{S_T - S}{S_T T_1} \right) \quad (23)$$

where S_T (m^2) is the total area of all surfaces in the room including the area of the material under test. It must be realized that the values obtained for $\bar{\alpha}$ are not a true measure of the energy absorption coefficient of the material for random incidence sound falling on the sample since many of the factors such as size and location of the sample influence the values obtained. We only really obtain a measure of the influence that the sample had on reverberation time of the test room.

In some circumstances it could be argued that the Sabine reverberation equation does not give accurate results and that perhaps some other formula such as the Eyring equation should be used. However, values of absorption coefficients listed by all manufacturers and testing laboratories are Sabine values calculated from Eq. (23). Provided the test room has a large volume and long reverberation time, and the test sound field is diffuse, the values obtained are usually fairly accurate. Nevertheless, despite the fact that measurements made in different reverberation rooms on the same absorbing sample often yield different values of absorption coefficient, the results of such tests have been used successfully by architectural acousticians in many situations.

A reverberation test room should have a large volume and long reverberation time to increase the acoustical modal density and decrease spatial variance in the sound field. To improve diffuseness, stationary or rotating vanes should be used. Since the effective absorption coefficient of a material depends to some extent upon its area,³¹ due to diffraction at its edges, it is necessary for the test sample to be sufficiently large so that diffraction effects are minimized.

The American Society for Testing and Materials (ASTM) has set a standard for such measurements.³² This standard covers the acoustical performance of the testing reverberant room and the sample size and mounting and governs the method for measuring the reverberation times. The room volume V should be greater than $4\lambda^2$, where λ is the longest wavelength used in the test. In addition, the smallest dimension of the room should exceed 2λ and the ratio of the largest to the smallest dimension should be less than 2 : 1. This therefore requires rooms to have volumes in excess of 10,000 ft^3 (283 m^3) in order to operate at 100 Hz.

The ASTM standard also specifies that the average absorption coefficient of the empty room at all test frequencies should not exceed 0.06, including the effect of air absorption. This requirement, together with the above volume restrictions, guarantees that the reverberation time of the whole usable frequency range (125 to 4000 Hz, octave bands) should be greater than 3.6 s, assuming a 2400- ft^2 (223 m^2) surface area. One-third octave bands of white or pink noise are used to create the sound field in the room, and the slope of the resultant sound pressure level decay curve

should be measured over a decay range of not less than 30 dB, starting from at least 5 dB down from the beginning of the decay. The test sample should be not less than 48 ft^2 (4.5 m^2), although sample areas of 72 ft^2 (6.7 m^2) are recommended. The measured absorption coefficients should be rounded off to the nearest multiple of 0.01, while the NRC (average of 250 to 2000 Hz) should be rounded to a NRC of 0.05.

The International Organization for standardization (ISO) also has set a testing standard for reverberation room absorption testing.³³ The size of the testing chamber is again governed by the lowest test frequency desired, but in order to measure down to 100 Hz the room should be in excess of 225 m^3 (7945 ft^3) and also satisfy $V > L^3/6.8$, where L is the greatest diagonal length of the room. The sample size is restricted to rectangular plane samples of area from 10 to 12 m^2 (i.e., 108 to 130 ft^2). Strips of materials are to be avoided, and the ratio of sample length to breadth must be not less than 0.7. The reverberation times of the test room itself must exceed 5 s at 125, 250, and 500 Hz, 4.5 s at 1000 Hz, 3.5 s at 2000 Hz, and 2 s at 4000 Hz. Either one-third or one-half octave bands of white noise may be used and warble tones may also be used, provided the frequency of deviation from the tone is $\pm 10\%$ for ≤ 500 Hz and ± 50 Hz for ≥ 500 Hz—the modulation frequency being set at 6 Hz. The use of stationary or rotating vane diffusers is again recommended.

Tables of absorption coefficients are published for a variety of acoustical materials in which numerous mounting systems are employed. Sound absorption coefficients and corresponding values of NRC of some common sound-absorbing materials and construction materials are shown in Table 2. More extensive tables of sound absorption coefficients of materials can be found in the literature. The book by Trevor Cox provides a good review on sound-absorbing materials.³⁴ The tables are very often made up after receiving absorption results from a number of independent testing laboratories for the same sample of material. It is found that even when all of the requirements of either the ISO or ASTM standards are met, quite large differences can still be observed between the values obtained for the absorption coefficients measured in different laboratories for the same sample.³⁵ These differences can be due to variations in the diffuseness of the testing rooms and to human error and bias in measuring the reverberation times.

5.2 Using Impedance Tubes

The standing wave or impedance tube provides a convenient laboratory method of measuring both the complex acoustic impedance and acoustic absorption coefficient of small samples for sound waves normally incident upon their surfaces.^{36,37} Because of the sample size restrictions, this method is only useful for porous materials and some resonant perforated absorbers. It cannot be used for resonant panels or large slit resonators since their absorption characteristics depend upon the size of the sample.

Table 2 Sound Absorption Coefficient $\alpha(f)$ and Corresponding NRC of Common Materials

Material	Frequency (Hz)						NRC
	125	250	500	1000	2000	4000

The sample material is placed in front of a heavy rigid termination at one end of a rigid walled tube (see Fig. 15), while a loudspeaker is mounted on the tube axis at the other end. The loudspeaker is fed with pure-tone signals (at one-third octave center frequencies) and this then radiates plane waves down the tube toward the sample; as long as the diameter of the tube is small compared with the sound wavelength, transverse modes cannot be set up within the tube. The plane waves are then partially reflected by the sample and travel back along the tube toward the loudspeaker. This results in a longitudinal interference pattern consisting of standing waves set up within the tube. A microphone connected to an extension probe tube is moved along the axis to measure the variation in sound pressure within the standing-wave tube. From measurements of the ratio of maximum to minimum sound pressure within the tube, the absorption coefficient of the sample, at normal incidence, can be calculated.

The *standing-wave ratio*, n , is defined as the ratio of maximum to minimum sound pressures within the

Figure 15 Standing-wave apparatus used to determine both the normal incidence absorption coefficient and complex impedance of a sample of material placed at the end of the tube.

tube. Thus, the normal incidence absorption coefficient is given by

$$\alpha = \frac{4n}{(n+1)^2} \quad (24)$$

It is found that the normal incidence absorption coefficient values measured in an impedance tube

are generally lower than the random incidence values obtained from the reverberation room method. At low frequencies the difference is only slight, while at high frequencies the tube values are generally 50% lower than those measured in a room.

To ensure plane waves, and therefore no transverse waves in the tube, the length of the tube shall exceed $\lambda/4$ and the diameter of the tube shall not exceed 0.58λ . Hence a 4-in. (10-cm) diameter, 3-ft (91-cm) long tube would have a useful range of 90 to 1800 Hz. To make measurements over the range of 90 to 6000 Hz, two different size tubes are required, a smaller one for high frequencies and a larger one for low frequencies.

In addition, by measuring the distance between the sample and the first standing-wave minimum sound pressure, then the complex acoustic impedance of the specimen can also be calculated. The relationship between the statistical absorption coefficient and complex impedance has been discussed in the literature.³⁸

More recently a technique to measure the complete spectrum of both the sound absorption coefficient and complex acoustic impedance has been developed and standardized.^{39,40} This technique, usually called the *two-microphone method*, allows one to obtain rapidly the data by using a broadband sound source in a shortened tube. The tube has a number of fixed microphones (see Fig. 16), and the transfer function between two microphone positions is measured using a signal analyzer. Thus, the complex pressure reflection coefficient as a function of frequency is obtained as

$$R = \frac{H_{12} - e^{-jk\delta}}{e^{jk\delta} - H_{12}} e^{j2kz} \quad (25)$$

where H_{12} is the transfer function between microphone position 1 and 2, δ is the microphone spacing, z is the distance shown in Fig. 16, and k is the free-field wavenumber. Then, the sound absorption coefficient is obtained as $\alpha = 1 - |R|^2$.

Equation (25) shows that the reflection coefficient cannot be determined at discrete frequency points for which the microphone spacing is almost equal to an integer multiple of $\lambda/2$. Therefore, the microphone spacing must be chosen such that $\delta \leq \lambda/2$. For a given microphone spacing, the measurement of sound absorption coefficients will be valid for frequencies for which $0.05c/\delta < f < 0.45c/\delta$. In addition, a careful calibration is required for the measured transfer function. One of the ways of doing it is the microphone switching procedure, which prevents the error due to phase mismatch and gain factor between the two measurement channels.⁴⁰

6 APPLICATIONS

The main applications of sound absorbent materials in noise control are⁴¹: (1) incorporation in noise control enclosures, covers, and wrappings to reduce reverberant buildup of sound and hence increase insertion loss (see Chapter 56), (2) incorporation in flow ducts to attenuate sound from fans and flow control devices (see Chapter 112), (3) application to the surfaces of rooms to control reflected sound (e.g., to reduce steady-state sound pressure levels in reverberant fields), (4) in vehicles (walls, engine compartments, engine exhaust, see Chapter 94), (5) in lightweight walls and ceilings of buildings, and (6) on traffic noise barriers to suppress reflections between the side of the vehicle and the barrier or to increase barrier performance by the presence of absorbent on and around the top of the barrier (see Chapter 58).

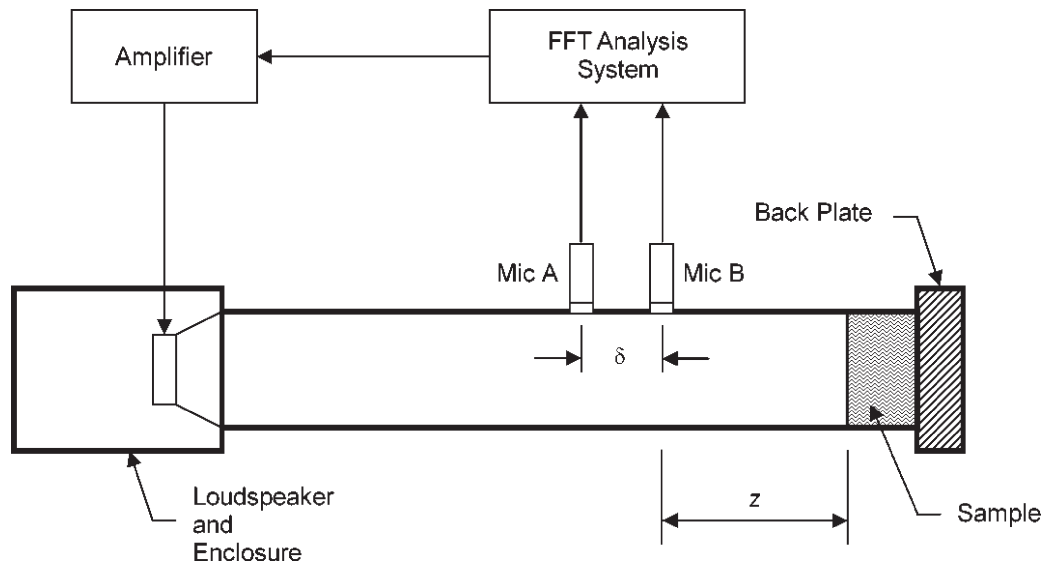

Figure 16 Experimental setup for the two-microphone method.

However, sound-absorbing materials are most commonly used to optimize the reverberation time in rooms and to reduce the sound pressure level in reverberant fields. These applications will now be described separately.

6.1 Optimization of the Reverberation Time

When sound is introduced into a room, the reverberant field level will increase until the sound energy input is just equal to the sound energy absorption. If the sound source is abruptly turned off, the reverberant field will decay at a rate determined by the rate of sound energy absorption.

As mentioned before, the reverberation time of a room depends upon the absorption present within it. In addition, the reverberation time has become recognized as the most important single parameter used to describe the acoustical performance of auditoriums. Changes in the total absorption can be made by modifying the values of areas and sound absorption coefficients of the room surfaces. Therefore, it is possible to change the values of reverberation time to provide players and listeners with a high degree of intelligibility throughout the room and optimum sound enrichment.

In a room, to understand speech fully, each component of the speech must be heard by the listener. If the room has a long reverberation time, then the speech components overlap and a loss of intelligibility results. Similarly, for music enjoyment and appreciation, a certain amount of reverberation is required to obtain the quality and blend of the music. It is, however, much more difficult to describe the acoustical qualities of a room used for music since many are subjective and therefore cannot be described in measurable physical quantities. Optimum reverberation time is not only required for good subjective reception but also for an efficient performance.

Optimum values of the reverberation time for various uses of a room may be calculated approximately by⁴²

$$T_R = K(0.0118V^{1/3} + 0.1070) \quad (26)$$

where T_R is the reverberation time (s), V is the room volume (m^3), and K is a constant that takes the following values according to the proposed use: For speech $K = 4$, for orchestra $K = 5$, and for choirs and rock bands $K = 6$. It has been suggested that, at frequencies in the 250-Hz octave band and lower frequencies, an increase is needed over the value calculated by Eq. (26), ranging from 40% at 250 Hz to 100% at 63 Hz. Other authors have suggested optimum T_R for rooms for various purposes.^{3,4}

However, achieving the optimum reverberation time for a room may not necessarily lead to good speech intelligibility or music appreciation. It is essential to adhere strictly to the other design rules for shape, volume, and time of arrival of early reflections.^{43,44}

Example 3 Consider an auditorium of dimensions $9 \text{ m} \times 20 \text{ m} \times 3.5 \text{ m}$, with an average Sabine absorption coefficient $\bar{\alpha} = 0.9$ for the whole room surface at 4000 Hz. Then the total surface area of the room is calculated as $S = 2(20 \times 3.5 + 9 \times 3.5 + 9 \times 20) = 563 \text{ m}^2$ and its volume is $V = 630 \text{ m}^3$. Assuming that there is a uniform distribution of absorption throughout the room, the reverberation time can be obtained as given by Sabine $T_R = 0.161V/(S\bar{\alpha}) = (0.161 \times 630)/(563 \times 0.9) = 0.2 \text{ s}$. Now substituting the value of room volume in Eq. (26), and considering $K = 4$ for using the room for speech, we obtain $T_R = 0.2 \text{ s}$. Therefore, the total absorption of such a room is optimum for its use as an auditorium, at least at 4000 Hz. This calculation may be repeated at each frequency for which absorption coefficient data are available.

6.2 Reduction of the Sound Pressure Level in Reverberant Fields

When a machine is operated inside a building, the machine operator usually receives most sound through a direct path, while people situated at greater distances receive sound mostly through reflections. In the case of machinery used in reverberant spaces such as factory buildings, the reduction in sound pressure level L_p in the reverberant field caused by the addition of sound-absorbing material, placed on the walls or under the roof (see Fig. 13), can be estimated for a source of sound power level L_W from the so-called room equation:

$$L_p = L_W + 10 \log \left(\frac{D}{4\pi r^2} + \frac{4}{R} \right) \quad (27)$$

where the room constant $R = S\bar{\alpha}/(1 - \bar{\alpha})$, $\bar{\alpha}$ is the surface average absorption coefficient of the walls, D is the source directivity, and r is the distance in metres from the source. The surface average absorption coefficient $\bar{\alpha}$ may be estimated from

$$\bar{\alpha} = \frac{S_1\alpha_1 + S_2\alpha_2 + S_3\alpha_3 + \dots}{S_1 + S_2 + S_3 + \dots} \quad (28)$$

where S_1, S_2, S_3, \dots are the surface areas of material with absorption coefficients $\alpha_1, \alpha_2, \alpha_3, \dots$, respectively. For the suspended absorbing panels shown in Fig. 13, both sides of the panel are normally included in the surface area calculation.

If the sound absorption is increased, then from Eq. (27) the change in sound pressure level ΔL in the reverberant space (beyond the critical distance r_c) is

$$\Delta L = L_{p1} - L_{p2} = 10 \log \frac{R_2}{R_1} \quad (29)$$

If $\bar{\alpha} \ll 1$, then the reduction in sound pressure level (sometimes called *the noise reduction*) is given by

$$\Delta L \approx 10 \log \frac{S_2\bar{\alpha}_2}{S_1\bar{\alpha}_1} \quad (30)$$

where S_2 is the total surface area of the room walls, floor, and ceiling and any suspended sound-absorbing material, $\bar{\alpha}_2$ is the average sound absorption coefficient of these surfaces after the addition of sound-absorbing material, and S_1 and $\bar{\alpha}_1$ are the area and the average sound absorption coefficient before the addition of the material.

Example 4 A machine source operates in a building of dimensions $30 \text{ m} \times 30 \text{ m}$ with a height of 10 m . Suppose the average absorption coefficient is $\bar{\alpha} = 0.02$ at 1000 Hz . What would be the noise reduction in the reverberant field if 100 sound-absorbing panels with dimensions $1 \text{ m} \times 2 \text{ m}$ each with an absorption coefficient of $\alpha = 0.8$ at 1000 Hz were suspended from the ceiling (assume both sides absorb sound)? The room surface area $= 2(900) + 4(300) = 3000 \text{ m}^2$, therefore $R_1 = (3000 \times 0.02)/0.98 = 60/0.98 = 61.2 \text{ sabins (m}^2\text{)}$. The new average absorption coefficient $\bar{\alpha}_2 = (3000 \times 0.02 + 200 \times 2 \times 0.8)/3400 = 0.11$. The new room constant is $(3400 \times 0.11)/0.89 = 420 \text{ sabins (m}^2\text{)}$. Thus from Eq. (29) the predicted noise reduction $\Delta L = 10 \log(420/61.2) = 8.3 \text{ dB}$. This calculation may be repeated at each frequency for which absorption coefficient data are available. It is normal to assume that about 10 dB is the practical limit for the noise reduction that can be achieved by adding sound-absorbing material in industrial situations.

7 ADDITIONAL CONSIDERATIONS

For each application of sound absorptive materials, not only the sound absorption coefficient (or NRC) has to be taken into account for the particular design. Specifications require that the material also be rated for flame spread and fire endurance, usually by use of a standardized test. In addition, consideration of dimensional stability, light reflectance, appearance, weight, maintenance, cleanliness, and cost is required in practice.³⁰ Most of these considerations are undertaken by the manufacturer.

To prevent the absorptive material from getting contaminated, a splash barrier should be applied over the absorptive lining. This should be a very light material such as one-mil plastic film (see Section 4.3.1). The surface of the absorptive layer may be retained for mechanical strength with expanded metal, perforated sheet metal, hardware cloth, or wire mesh. However, the retaining material should have at least 25% open area.⁴⁵

In certain applications (e.g., in the use of absorbing materials in mufflers for ventilation systems) it could be necessary to employ less porous materials such as ceramic absorbers, which have the advantages of much better durability, mechanical strength, and refractory properties. Particular care has to be taken with the use of synthetic mineral wools since they are irritants. These materials could cause long-term health effects for those working in the manufacture of these products.⁴⁶ On the other hand, the use of recycled materials to make absorbers has recently been investigated, showing some promising results, in

particular, for granulated mixes of waste foam⁴⁷ and small granules of discarded rubber from tires.⁴⁸

The sound-absorbing properties of porous road pavements have been studied by Crocker and Li⁴⁹ to reduce interstate highway noise of automobiles. To evaluate the effect of different thicknesses, slabs were manufactured in the laboratory. The slabs consisted of a 6.35-mm dense graded Superpave mix with a fine 9.5-mm open graded fine core (OGFC) placed on top. Three different thickness layers were used (2.6 , 3.8 , and 5.1 cm). Figure 17 shows the experimental results of absorption coefficient of OGFC samples measured using the technique described in Section 5.2. It can be observed that the thickness of the porous surface has a large effect on the sharpness of the peaks. Generally, the thicker the porous surface the lower is the peak frequency. With thicker porous surfaces the peaks generally also become broader and the peak absorption

Figure 17 Sound absorption coefficient of a slab of dense graded Superpave mix with a fine open graded fine core of different thicknesses (t) placed on top.

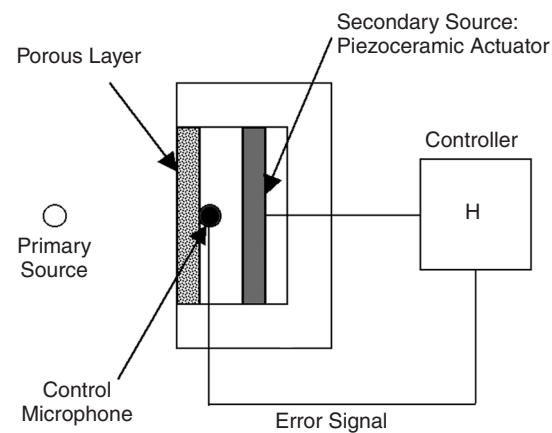

Figure 18 Hybrid passive/active absorber cell.

is somewhat reduced. For the 5.1-cm sample, the peak frequency is about 900 Hz, which coincides with the noise generated by automobiles in interstate travel. In addition, the sound absorption peak is fairly broad, so it is attractive to use such a porous surface to reduce noise.

More recently, the use of active noise control (see Chapter 63) has been combined with passive control to develop hybrid absorbers. Active control technologies appear to be the only way to attenuate the low-frequency noise components. Therefore, a hybrid passive/active absorber can absorb the incident sound over a wide frequency range. Figure 18 shows the principle of such a device, which combines passive absorbent properties of a porous layer and active control at its rear face, and where the controller can be implemented using digital techniques.^{50,51} The use of a piezoelectric actuator as a secondary source and wire meshes as porous material has allowed the design of thin active liners, composed of several juxtaposed cells of absorbers, to be used in the reduction of noise in flow ducts.⁵¹ On the other hand, the combination of active and passive control using microperforated panels has given promising results to be applied in absorbers systems.⁵²

CHAPTER 58

USE OF BARRIERS

Jorge P. Arenas

Valdivia, Chile

1. INTRODUCTION

A barrier is a device designed to reflect most of the sound energy incident back toward the source of sound. The use of barriers to control noise problems is an example of a practical application of a complicated physical theory: the theory of diffraction, a physical phenomenon that corresponds to the nonspecular reflection or scattering of sound waves by an object or boundary. Most of the theories of diffraction were originally formulated for optics, but they find many applications in acoustics. Several models and design charts have been partly developed from these theories.

In particular, noise barriers are a commonly used measure to reduce the high levels of environmental noise produced by the traffic on highways. For their proper use, aspects of design, economics, materials, construction details, aesthetic, and durability must be considered to ensure good performance. The fundamentals of the diffraction at the edge of a thin semi-infinite, acoustically opaque plane barrier may be considered as the basis for all subsequent applications. Barriers are used both indoors and outdoors in some applications.

2 BASIC THEORY

2.1 Insertion Loss of Barriers

Since the pioneering works on barrier diffraction of Sommerfeld, Macdonald,¹ and others, several

models to predict the acoustics of barriers have been developed. Design charts of Fehr,² Maekawa,³ and Rathe⁴ plus the physical and geometrical theories have made possible the development of some equations and convenient algorithms to predict the attenuation of simple barriers. The key work of Kurze and Anderson⁵ simplified the task of calculating the attenuation by the use of geometrical parameters, such as Fresnel number.

As in the diffraction of light waves, when the sound reaches a listener by an indirect path over a barrier, there is a shadow zone and a bright zone, as shown in Fig. 1. However, the diffracted wave coming from the top edge of the barrier affects a small transition region close to the shadow zone by interfering with the direct wave.⁶

In 1957 Keller proposed the geometric theory of diffraction (GTD) for barriers, which has been employed in the formulation of many different physical problems.⁷ Basically, he stated that from the set of diffracted sound rays from the barrier edge, the ray that reaches the reception point corresponds to the ray that satisfies Fermat's principle.

This geometrical theory of diffraction leads to relatively simple formulas, which combine the practicability of Kirchhoff's approximations with the greater accuracy of the Sommerfeld-type solutions and can be generalized to treat diffraction by three-dimensional

Figure 1 Diffraction by a rigid barrier.

Figure 2 Geometry used in the theory of diffraction.

objects of any smooth shape.⁸ The geometrical situation is sketched in Fig. 2. For an infinite extended and very thin semiplane, and assuming no reflections on the ground, the diffracted sound pressure amplitude is

$$\Psi = \frac{-1}{2\sqrt{2\pi k}} \frac{Q(\phi, \phi_s)}{\sqrt{rr_s(r+r_s)}} \exp \left\{ i \left(k[r+r_s] + \frac{\pi}{4} \right) \right\} \quad (1)$$

where r_s is the distance between the source and the top of the plane, r is the distance between the top of the plane and the reception point, k is the free-field wave number, and

$$Q(\phi, \phi_s) = \frac{1}{\cos \frac{1}{2}(\phi + \phi_s)} + \frac{1}{\cos \frac{1}{2}(\phi - \phi_s)} \quad (2)$$

The function $Q(\phi, \phi_s)$ implies that the edge of the plane radiates sound as a directional sound source. Equation (1) must include the term $1/\sqrt{2\pi k}$ to describe in a correct way the directivity of the diffracting edge when it is considered as a secondary source (frequency dependent). The sum in Eq. (2) corresponds to contributions from the source and its image due to reflection at the barrier. In addition, from Eq. (1) it is observed that for a fixed value of r_s , which satisfies the condition $kr_s > 1$, the amplitude of the sound wave is proportional to $1/\sqrt{r}$ for points located close to the diffracting edge. This implies cylindrical divergence and thus a decay of 3 dB per doubling of distance.

On the other hand, for points far away from the edge, the amplitude will be proportional to $1/r$, that is, spherical divergence. Therefore, the sound pressure level will decay 6 dB per doubling the distance. This important fact can also be obtained from the asymptotic analysis of the physical solution obtained by Macdonald.¹ To obtain the insertion loss (IL) from Keller's theory, the ratio between Eq. (1) and the sound pressure amplitude for a spherical wave propagating with free-field conditions has to be found. The attenuation in decibels from Keller's theory is given by

$$IL_K = -10 \log \left[\frac{d^2}{8k\pi rr_s(r+r_s)} |Q(\phi, \phi_s)|^2 \right] \quad (3)$$

where d is the straight line distance between the source and the reception point (see Fig. 2).

Certainly, from a practical point of view, most of the applications of the physical and geometrical theory had been difficult to use due to the complexity of the analysis, which does not permit fast calculation for design purposes. Because of this, several algorithms, charts, and plots have been developed from time to time. One of the most well-known simplifications was proposed by Redfearn in 1940.⁹ A design chart was presented where the graphical relationship between the attenuation and the parameter h/λ can be read. The parameter h corresponds to the "effective height" of the barrier and λ is the wavelength of the incident sound wave. The parameter h/λ is usually known as the Redfearn parameter and it can be shown that

$$\frac{h}{\lambda} = \frac{rr_s}{\lambda d} \sin \phi \quad (4)$$

Since a rigorous solution of the diffraction problems involve several parameters in its formulation, it is clear that the approximations using the Redfearn chart could involve large errors.

In 1971 Kurze and Anderson reported a seminal study that presented one algorithm widely used today.⁵ This algorithm was obtained by comparing the experimental results of Rathe⁴ and Redfearn⁹ and the geometric theory of diffraction. Their final equation can be derived from the Redfearn parameter. In fact, considering Eqs. (1) and (2) and the geometrical relationships between ϕ , ϕ_s , and φ , the insertion loss (the difference of the sound pressure levels at the receiving point with and without the screen present), can be expressed as

$$IL_K = 10 \log \left[8\pi^2 \frac{h}{\lambda} \tan \left(\frac{\varphi}{2} \right) \right] - 10 \log \frac{d}{r+r_s} - 20 \log \left[1 + \frac{\sin(\varphi/2)}{\sin(\phi + \varphi/2)} \right] \quad (5)$$

where

$$\varphi = \arccos \frac{d_s d_r + h h_r - h^2}{\sqrt{[d_r^2 + (h - h_r)^2][d_s^2 + h^2]}} \quad (6)$$

and

$$\phi = \arcsin \frac{d_r}{\sqrt{d_r^2 + (h - h_r)^2}} \quad (7)$$

according to the geometry shown in Fig. 2.

For $\varphi > \pi/4$, the first term of Eq. (5) gives a good approximation to the results of Rathe. The second term is very small for perpendicular incidence $\phi_s = 3\pi/2$, and it could be very large for close positions of the source and receiver to the screen. The third term is small for small angles of diffraction, but it has to be considered when the receiver or the source is close to the barrier. Maekawa³ presented a chart based on the physical theory of diffraction and also

numerous experimental results. His chart gave values of attenuation versus the dimensionless Fresnel number defined as

$$N = \pm \frac{2}{\lambda} \delta = \pm \frac{2}{\lambda} (r_s + r - d) \quad (8)$$

where δ is called the path length difference. The \pm is used to indicate the corresponding zone, such that N is positive in the shadow zone and negative in the bright zone.

Now, the Fresnel number, in terms of the geometry shown in Fig. 2, can be calculated as

$$N = \sqrt{d_s^2 + h^2} + \sqrt{d_r^2 + (h - h_r)^2} - \sqrt{h_r^2 + (d_s + d_r)^2} \quad (9)$$

For values of $N > 1$, Maekawa's result for insertion loss can be approximated by $13 + 10 \log N$. When $\varphi \ll 1$ and $d \rightarrow r + r_s$, the insertion loss can be approximated by $5 + 10 \log 4\pi N$.

However, to find a more reliable expression for attenuation, Kurze and Anderson⁵ modified the results of the last expression and obtain an analytical-empirical equation known as the Kurze-Anderson algorithm given by

$$IL_{KA} = 5 + 20 \log \frac{\sqrt{2\pi N}}{\tanh \sqrt{2\pi N}} \quad (10)$$

Equation (10) gives good results in practice for $N > 0$ and it shows good agreement with the experimental results obtained by Maekawa,³ for values of attenuation up to 24 dB (see Fig. 3). Equation (10) has been the starting point to define most of the barrier design algorithms used today to mitigate the impact of noise from highways.

Figure 3 Attenuation of the sound from a point source by a rigid screen as a function of Fresnel number.

2.2 Transmission Loss of Barriers

Barriers are a form of partial enclosure (they do not completely enclose the source or receiver) to reduce the direct sound field radiated in one direction only. The barrier edges diffract the sound waves, but some waves can pass through the barrier according to the sound transmission laws. All the theories of diffraction have been developed assuming that the transmission loss of the barrier material is sufficiently large that transmission through the barrier can be ignored. Obviously, the heavier the barrier material, or the higher the frequency, the greater the transmission loss for sound going through the barrier.

A generally applicable acoustical requirement for a barrier material is to limit the component of sound passing through it to 10 dB less than the predicted noise level due to sound diffracted over the barrier. Evidently, this is not a governing criterion for concrete or masonry, but can be important for light aluminum, timber, and for glazing panels. In addition, this may be an important consideration when designing "windows" in very tall barriers.

In a study on barriers used indoors, Warnock compared the transmitted sound through a barrier with the diffracted sound over the barrier.¹⁰ He found that the transmitted sound is negligible if the surface density of a single screen satisfies the criterion $\rho_s = 3\sqrt{\delta}$ kg/m². The minimum acceptable value of ρ_s corresponds to the transmission loss at 1000 Hz being 6 dB higher than the theoretical diffraction loss. A formula for calculating the minimum required surface density for a barrier is¹¹

$$\rho_s = 3 \times 10^{(A-10/14)} \text{ kg/m}^2 \quad (11)$$

where A is the A-weighted potential attenuation of the barrier in decibels when used outdoors.

As a general rule, when the barrier surface density ρ_s exceeds 20 kg/m², the transmitted sound through the barrier can be ignored, and then the diffraction sets the limit on the noise reduction that may be achieved.

According to the discussion above, when butting or overlapping components assemble a noise barrier, it is important that the joints be well sealed to prevent leakage. As an indication, it is common for timber barriers to be manufactured from 19-mm-thick material. As indicated by the mass law, this provides a sound reduction index of 20 dB if joints are tight, which is quite sufficient for barriers designed to provide an attenuation of 10 dB. In some countries, the legislation requires a sample of barrier to be tested in accordance with the local standard for sound insulation of partitions in buildings.

3 USE OF BARRIERS INDOOR

Single-screen barriers are widely used in open-plan offices (or landscaped offices) to separate individual workplaces to improve acoustical and visual privacy. The basic elements of these barriers are freestanding screens (partial-height partitions or panels). However,

when placing a sound barrier in a room, the reverberant sound field and reflections from other surfaces cannot be ignored.

The diffraction of the sound waves around the barrier boundaries alters the effective directivity of the source [see Eq. (2)]. For a barrier placed in a rectangular room, if the receiver is in the shadow zone of the barrier and the sound power radiated by the source is not affected by insertion of the barrier, the approximate insertion loss can be calculated by¹²

$$IL = 10 \log \left(\frac{\frac{Q_\theta}{4\pi r^2} + \frac{4}{S_0 \alpha_0}}{\frac{Q_B}{4\pi r^2} + \frac{4\Gamma_1 \Gamma_2}{S(1 - \Gamma_1 \Gamma_2)}} \right) \quad (12)$$

where Q_θ is the source directivity factor, $S_0 \alpha_0$ is the room absorption for the original room before placing the barrier, S_0 is the total room surface area, α_0 is the mean room Sabine absorption coefficient, S is the open area between the barrier perimeter and the room walls and ceiling,

$$Q_B = Q_\theta \sum_{i=1}^n \left(\frac{1}{3 + 10N_i} \right) \quad (13)$$

is the effective directivity, n is the number of edges of the barrier (e.g., $n = 3$ for a freestanding barrier, see Fig. 4), and Γ_1 and Γ_2 are dimensionless numbers related to the room absorption on the source side ($S_1 \alpha_1$) and the receiver side ($S_2 \alpha_2$) of the barrier, respectively, as well as the open area, and given by

$$\Gamma_1 = \frac{S}{S + S_1 \alpha_1} \quad \text{and} \quad \Gamma_2 = \frac{S}{S + S_2 \alpha_2} \quad (14)$$

Figure 4 Freestanding barrier used indoors and the three diffraction paths.

Therefore, $S_1 + S_2 = S_0$ + (area of two sides of the barrier) and α_1 and α_2 are the mean Sabine absorption coefficients associated with areas S_1 and S_2 , respectively.

It has to be noticed that when the barrier is located in a highly reverberant field the IL tends to zero, which means that the barriers are ineffective in highly reverberant environments. Consequently, in this case the barrier should be treated with sound-absorbing material, increasing the overall sound absorption of the room.

The approximation for the effective directivity given in Eq. (13) is based on Tadge's result.¹³ In deriving Eq. (12) the interference between the sound waves has been neglected, so Eq. (12) predicts the insertion loss accurately when octave-band analysis is used. However, the effects of the reflections in the floor and the ceiling are not taken into account. This effect will be discussed later. In general, the ceiling in an open-plan office must be highly sound absorptive to ensure maximum performance of a barrier. This is particularly important at those frequencies significant for determining speech intelligibility (500 to 4000 Hz).

A more general model for calculating the insertion loss of a single-screen barrier in the presence of a floor and a ceiling has been presented by Wang and Bradley.¹⁴ Their model was developed using the image source technique.

Recently, a new International Organization for Standardization standard has been published on the guidelines for noise control in offices and workrooms by means of acoustical screens.¹⁵ The standard specifies the acoustical and operational requirements to be agreed upon between the supplier or manufacturer and the user of acoustical screens. In addition, the standard is applicable to (1) freestanding acoustical screens for offices, service areas, exhibition areas, and similar rooms, (2) acoustical screens integrated in the furniture of such rooms, (3) portable and removable acoustical screens for workshops, and (4) fixed room partitions with more than 10% of the connecting area open and acoustically untreated.

4 USE OF BARRIERS OUTDOORS

The use of barriers outdoors to control the noise from highways is surely the most well-known application of barriers. While noise barriers do not eliminate all highway traffic noise, they do reduce it substantially and improve the quality of life for people who live adjacent to busy highways. Noise barriers include walls, fences, earth berms, dense plantings, buildings, or combinations of them that interrupt the line-of-sight between source and observer. It appears that construction of barriers is the main alternative used for the reduction of noise, although quiet road surfaces, insulation of properties, or use of tunnels have also been used for this purpose.

The theory discussed so far has been established for point or coherent line sources. However, the sound radiated from a highway is composed for several incoherent moving sources (vehicles of different

types). It has been shown⁶ that when a noise source approximates to an incoherent line source (stream of traffic), then the insertion loss is about 5 dB lower than the one calculated for a point source. From field results it has also been observed that earth berms (mounds of earth) produce about 3 dB more attenuation than walls of the same height. Then, predicted barrier attenuation values will always be approximations.

Attenuation other than resulting from wave divergence is called excess attenuation. Noise reduction due to a barrier is considered as a reduction to be added to other reductions due to such effects as spherical spreading, attenuation by absorption in the air, wind and temperature gradients, presence of grass and trees, and the like. Therefore, it is common to refer to the excess attenuation by a barrier instead of insertion loss of barriers.

4.1 Finite Barrier

If a barrier is finite in length (as the barriers used indoors), flanking (noise traveling around the ends of the barrier) will reduce the attenuation. In highway applications, it is recommended that the minimum angle of view that should be screened to avoid flanking is 160°. This means that to effectively reduce the noise coming around its ends, a barrier should be at least eight times as long as the distance from the home or receiver to the barrier.

For a barrier finite in length, parallel to a highway, and located between the highway and the observer, as shown in Fig. 5, the approximate A-weighted attenuation in decibels is given by¹⁶

$$A = 10 \log \left(\frac{1}{\beta_2 - \beta_1} \int_{\beta_1}^{\beta_2} 10^{A(\beta)/10} d\beta \right) \quad (15)$$

where β is the angular position of the source from a perpendicular drawn from the observer to the highway, $A(\beta)$ is a function given by:

1. For $N_{\max} \cos \beta \leq -0.1916 - 0.0635b^*$,

$$A(\beta) = 0 \quad (16a)$$

2. For $-0.1916 - 0.0635b^* < N_{\max} \cos \beta \leq 0$,

$$A(\beta) = 5(1 + 0.6b^*) + 20 \log \frac{\sqrt{-2\pi N_{\max} \cos \beta}}{\tan \sqrt{-2\pi N_{\max} \cos \beta}} \quad (16b)$$

3. For $0 < N_{\max} \cos \beta < 5.03$,

$$A(\beta) = 5(1 + 0.6b^*) + 20 \log \frac{\sqrt{2\pi N_{\max} \cos \beta}}{\tan \sqrt{2\pi N_{\max} \cos \beta}} \quad (16c)$$

4. For $N_{\max} \cos \beta \geq 5.03$,

$$A(\beta) = 20(1 + 0.15b^*) \quad (16d)$$

N_{\max} is the Fresnel number when the source-to-observer path is perpendicular to the barrier, and b^* is the berm correction (0 for a freestanding wall or 1 for an earth berm). Thus, for an infinite barrier, $\beta_1 = -\pi/2$ and $\beta_2 = \pi/2$.

The noise attenuation of a finite barrier calculated by Eq. (15) includes just the segment of incoherent source line that the receiver cannot see. Then, the contribution to the total noise of the segments not covered by the barrier should be estimated accordingly.¹⁷

It is possible to calculate Eq. (15) for each frequency band. However, to save time, an effective radiating frequency of 550 Hz is, in general, used as representative of a normalized A-weighted noise spectrum for traffic over 50 km/h.^{18,19} Then, the Fresnel number can be evaluated as $N = 3.21 \times \delta$. Under this assumption, the A-weighted barrier attenuation in decibels for an infinite freestanding wall, as a function of δ , is shown in Fig. 6.¹⁷

4.2 Nonparallel Barrier

For evaluating the attenuation of a barrier not parallel to an incoherent source line, it is necessary to determine

Figure 5 Top view of the finite barrier parallel to a highway.

Figure 6 A-weighted attenuation for traffic noise as a function of path difference.

Figure 7 Geometry for a barrier that is not parallel to the source line.

the equivalent path length difference (δ) that gives the effective source position.²⁰ The geometry is shown in Fig. 7. First, a line bisecting the angle θ is drawn from the receiver point to the top edge of the barrier (point O). Then, a line is drawn from point O parallel to the source line to meet the vertical plane (i.e., normal to the road surface), which passes through the receiver point R and the effective source position S at B .

Finally, the equivalent path difference is calculated as $\delta = SB + BR - SR$. The attenuation is then calculated for this equivalent δ .

4.3 Reflections on the Ground

When considering the reflections of sound on the ground, extra propagation paths are created that can result in increased sound pressure at the receiver. The geometry showing reflection on an acoustically hard ground for an infinite barrier is shown in Fig. 8. Application of the image source method indicates that a total of four diffraction paths must be considered: SOR , $SAOBR$, $SAOR$, and $SOBR$. Therefore, the attenuation and expected sound pressure level at the receiver has to be calculated for each of the four paths. Then, the four expected sound pressure levels are combined logarithmically to obtain the sound level with the barrier. The process is repeated for the pressure case without the barrier (which has just two paths) to calculate the combined level at the receiver before placing the barrier. Then, the insertion loss is determined as usual. If the

Figure 8 Image method for reflections on the ground.

barrier is finite, eight separate paths should be considered since the diffraction around the ends involves only one ground reflection.

Usually, the ground is somewhat absorptive. Therefore, the amplitude of each reflected path has to be reduced by multiplying its amplitude by the pressure reflection coefficient of the ground.^{17,21-24}

Other reflections can affect the performance of a barrier, in particular when dealing with parallel barriers. This is the case when barriers are constructed on both sides of a road or when the road is depressed with vertical retaining walls. To overcome this problem of multiple reflections and insertion loss degradation, it is possible to:

1. Increase the height of the barriers.
2. Use barriers with sound-absorbing surfaces facing the traffic [a noise reduction coefficient (NRC) greater than 0.65 is recommended].
3. Simply tilt the barriers outward (a tilt of 5° to 15° is usually recommended).

4.4 Thick Barrier

A barrier cannot always be treated as a very thin screen. An existing building can interrupt the line-of-sight between the source and a receiver acting as a thick barrier when its thickness is greater than the wavelength of the incident sound wave. Double diffraction at the two edges of a thick barrier may increase the attenuation. A simplified method to calculate the attenuation of a thick barrier is shown in Fig. 9. It is necessary to transform the thick barrier, of height H , into an equivalent thin barrier of height H' , and then to calculate its attenuation using the usual equations.

A more accurate method has been proposed.²⁵ The effect of the double diffraction is to add an additional term to the attenuation due to a thin barrier. In Fig. 9 the line $S'Y$ is parallel to the line SX . The attenuation of the thick barrier is

$$A = A_0 + K \log \frac{2\pi t}{\lambda} \quad (17)$$

Figure 9 Geometry for evaluating the attenuation of a thick barrier.

Figure 10 Thick barrier correction factor K for Eq. (17).

where A_0 is the attenuation of a thin barrier for which $\delta = S'Y + YR - d'$ (see Fig. 9), t is the barrier thickness, and K is a coefficient that can be estimated using Fig. 10.

4.5 Double Barrier

In some cases inclusion of a second barrier placed parallel to and behind the first is used to seek additional attenuation or because of design requirements, as in the case of emergency access and maintenance. Figure 11 shows a double barrier. It can be observed that the edge of the barrier closer to the source will become a secondary line source for the second barrier.

A method to calculate the effective attenuation of the double barrier has been presented by Foss,²⁶ and this method has been implemented in the traffic noise model of the Federal Highway Administration (FHWA).¹⁷ The effective attenuation is calculated by

$$A = F + J - \left\{ 6 \exp\left(\frac{-2W}{T}\right) + 1.3 \left[\exp\left(\frac{-35W}{T} - 1\right) \right] \right\} \times \left[1 - \exp\left(\frac{-J}{2}\right) \right] \quad (18)$$

Figure 11 Double-barrier geometry.

where the parameters are defined in Fig. 11, and F and J are calculated according to the Foss double-barrier algorithm. First, the attenuation is calculated for each barrier alone, ignoring the other. F is the higher of the two attenuations, and its associated barrier is designated as the "best" barrier. Then, depending on which is closer, either the source or the receiver is moved to the top of the best barrier. A modified barrier geometry is then drawn from the top of the best barrier over the other barrier to actual source or receiver. The attenuation for this modified geometry is J . Then, the effective attenuation is calculated using Eq. (18).

The screening effect in the sound propagation outdoors has been included in an ISO standard.²⁷ This standard includes equations for both single and double diffraction and a correction factor for meteorological effects to predict the equivalent continuous A-weighted sound pressure levels. On the other hand, the in situ determination of the insertion loss of outdoor noise barriers is also described by an ISO standard.²⁸

4.6 Additional Improvements

In certain applications it may be necessary to enhance the attenuation provided by a single barrier without increasing its height. One example of this would be the need to increase a barrier's effectiveness without further reducing the view for residents living alongside a road that would be caused by use of a higher barrier. All the studies show that the use of some kind of element over the top of the barrier or the modification of its profile will change the original diffracted sound field.²⁹ In some cases this alternative can produce a significant improvement of the attenuation.

Theoretical and experimental studies on diffracting-edge modifications include T- and Y-shaped barriers,³⁰⁻³² multiple-edge barriers,³³ and tubular caps and interference devices placed on top of barriers.³⁴⁻³⁶ Full-scale tests of the acoustical performance of new designs of traffic noise barriers have been reported by Watts et al.³⁷

Other options to improve the performance of a barrier are the use of modular forms of absorbing barriers,³⁸ absorbent edges,³⁹ and by developing random profiles of different heights and widths, depending on the acoustic wavelength that has to be taken into account.⁴⁰

However, these alternatives are still under research and, sometimes, it is difficult to compare the results between different studies since the barrier heights, source position, receiver position, and ground conditions are all different.

5 DESIGN ASPECTS

In the design of a barrier all of the relevant environmental, engineering, and safety requirements have to be considered. In addition to mitigate the impact of a highway, a barrier will become part of the landscape and neighborhoods. Therefore, some consideration has to be taken to assure a positive public reaction.

Both acoustical and landscape issues, to give guidance on good practice and design aspects, have been discussed widely in the technical literature.^{41,42}

Figure 12 Types of material used to construct barriers in the United States (until 1998).

5.1 Materials and Costs

A good design has to take into account that a barrier should require minimal maintenance other than cleaning or repair of damage for many years. Therefore, attention should be paid to the selection of materials used in the construction of barriers, in particular, for areas subject to extreme weather conditions. Noise barriers can be constructed from earth, concrete, masonry, wood, metal, plastic, and other materials or combination of materials. A report showed that until 1998 most barriers built in the United States have been made from concrete or masonry block, range from 3 to 5 m in height, and slightly more than 1% have been constructed with absorptive materials.⁴³ Figure 12 presents a comparison of the types of material used to construct barriers in the United States.

Evidently, concrete or masonry walls require little or no maintenance during the service life, but transparent sections need frequent cleaning and might well need replacing after some time. The durability of sound-absorbing materials for highway noise barriers has been discussed by some authors.⁴⁴

Often it is necessary to provide access from the protected side for maintenance purposes and for pedestrians or cyclists, which render a barrier vulnerable to vandalism. In addition, it may be advisable to avoid the use of flammable materials in some fire-risk areas and, in general, it may be appropriate to install fire-breaks to limit the spread of fire.⁴⁵ When plants are selected for use in conjunction with a barrier, they should generally be of hardy species (native plantings are preferable) that require a low level of maintenance.

A designer should seek detailed information for a specific project to estimate the cost of barrier construction and maintenance. This is particularly

important when cost effectiveness is a must for positive decision on the construction of a barrier, since in some countries governmental agencies and individual homeowners sometimes share the costs of noise barriers.

A broad indication of the relative costs, for a selection of typical forms of construction at a standard height of 3 m, is shown in Table 1.

Some additional aspects of the design of a barrier that need to be considered are the force caused by wind, aerodynamic forces caused by passing vehicles, the possibility of impact by errant vehicles, earthquakes, noise leaking through any gaps between elements or at the supports, and the effect of snow being thrown against the face of the barrier by clearing equipment.

5.2 Human Response

The public, increasingly well-informed about the problem of excessive noise, is taking actions on the development of new transport infrastructure projects and improvement to existing infrastructure.

Most of the residents near a barrier seem to feel that highway noise barriers effectively reduce traffic noise and that the benefits of barriers far outweigh the disadvantages of barriers. Some studies have shown that public reaction to highway noise barriers appears to be positive.⁴⁶ However, specific reactions vary widely. Residents adjacent to barriers have reported that conversations in households are easier, sleeping conditions are better, the environment is more relaxing, windows are opened more often, and yards are used more in the summer. In addition, residents perceived indirect benefits, such as increased privacy, cleaner air, improved views, a sense of ruralness, and healthier lawns. Negative reactions from residents have included a restriction of view, a feeling of confinement, a loss of air circulation, a loss of sunlight and lighting, and poor maintenance of the barrier.

On the other hand, motorists have sometimes complained of a loss of view or scenic vistas and a feeling of being "walled in" when traveling adjacent to barriers. High barriers substantially conceal the view of existing landmarks from the road, but they also conceal visual clutter, which might otherwise distract the attention of drivers. It is recommended that the appearance of barriers should be designed to avoid monotony. Surveys of drivers in Holland have indicated that a view that is unchanging for 30 s is monotonous.⁴² This suggests that changes in design of barrier face every 800 m are desirable for long barriers adjacent to a high-speed road.

Noise barriers should reflect the character of their surroundings or the local neighborhood as much as possible to be acceptable to local residents. It is always recommended to preserve aesthetic views and scenic vistas. The visual character of noise barriers in relationship to their environmental setting should be carefully considered. For example, a tall barrier near a one-story, single-family, detached residential area can have a negative visual effect. In general, it is recommended to locate a noise barrier approximately

Table 1 Construction and Maintenance Cost of Different Barriers

Barrier Type	Assumed Features of Design	Factors of Maintenance	Relative Cost of Construction	Relative Cost of Maintenance
Earth mound	Agricultural land price, landscape planting excluded Local source of fill assumed	Grass cutting, planting maintenance	Very low	Fairly low
Timber screen	Designed in accordance with current standards	Inspection/repair, periodic treatment	Low	Low
Concrete screen	Precast pier, beams, and panels	Inspection/repair, periodic cleaning	Fairly low	Very low
Brickwork/masonry wall	Standard facing brick	Inspection/repair, periodic cleaning/repainting	Moderate	Very low
Plastic/planted system	Plastic building "blocks" (planters)	Inspection/repair, periodic cleaning, planting maintenance, irrigation	Moderate	Moderate
Metal panels	Plastic-coated metal panels with steel supports	Inspection/repair, repainting/treatment Tighten bolts, check earthing	Moderate	Fairly low
Absorbent panels	Perforated (absorbent) metal panels with rockwool infill	Inspection/repair, periodic cleaning	Moderate	Fairly low
Transparent panels	Steel piers, etched glass panels	Inspection/repair, regular cleaning/treatment	Fairly high	Fairly high
Crib wall (concrete or timber)	Proprietary system or purpose designed High labor costs, agricultural land price	Inspection/repair	Very high	Low

four times its height from residences and to provide landscaping near the barrier to avoid visual dominance and reduce visual impact.⁴⁶

5.3 Computational Aid

There are a number of commercially available software programs to help in designing barriers. Most programs are designed to predict the noise levels produced by sources such as factories, industrial facilities, highways, railways, and the like. Their use is widely accepted in environmental impact studies when the solution of problems of high geometrical complexity is required.

The programs are, in general, able to compute the sound pressure level contours, insertion loss contours, and level difference contours. Some of these programs implement governmental approved models to predict traffic noise as well as more specialized enhancements. Then, problems involving diffraction by building rows, trees zone, parallel-barrier degradation for barriers, or retaining walls that flank a roadway are possible to solve. Some of the programs can make work much easier in that they incorporate vehicle noise emission databases. The results predicted by these programs agree quite well with experimental results since the

CHAPTER 59

USE OF VIBRATION ISOLATION*

Eric E. Ungar
Acentech Incorporated
Cambridge, Massachusetts

1 INTRODUCTION

Vibration isolation concerns the use of comparatively resilient elements—called vibration isolators—for the purpose of reducing the vibratory forces or motions that are transmitted from one structure or mechanical component to another. Practical vibration isolators usually consist of springs, of elastomeric elements, or of combinations of these. The primary purpose of isolators is to attenuate the transmission of vibrations, whereas the main purpose of dampers is the dissipation of mechanical energy.

Vibration isolation generally is employed (1) to protect a sensitive item of equipment from vibrations of a structure to which it is attached or (2) to reduce the vibrations that are induced in a structure by a machine that is attached to it. Reduction of structural vibrations may be desirable for reasons of structural integrity, human comfort, and control of noise radiated from structures, among others.

Simple models based on systems with a single degree of freedom are useful for establishing some fundamental relations. Extensions of these models can account for the nonrigidity of supports and isolated items, as well as for reaction effects on vibration sources. More complex models apply to the isolation

of masses that can rotate as well as translate and to two-stage isolation that can provide greater attenuation than single-stage isolation systems.

2 BASIC MODEL

Many aspects of vibration isolation can be understood on the basis of a simple model consisting of a mass that is connected to a support via an isolator, as shown in Fig. 1. In Fig. 1a the mass m represents a sensitive item that is to be protected from vibrational motion of the support S ; in Fig. 1b the support S is to be protected from a force that acts on it due to the vibrational force F_1 that acts on the mass m of a machine. In this basic model the mass can move only in translation along a straight line (in the vertical direction of the figure) and the isolator is taken to be a linear massless spring. The restoring force produced by such a spring is proportional to its deflection.

The *transmissibility* represents the fraction of the applied excitation that is transmitted to the part that is to be protected. In the case that corresponds to Fig. 1a, the concern is the transmitted motion, and the corresponding *motion transmissibility* is defined as $T_{\text{motion}} = X_m/X_s$, where X_m and X_s denote, respectively, the amplitudes of the motions of the mass and of the support. In the case that corresponds to Fig. 1b the *force transmissibility* is defined as $T_{\text{force}} = F_s/F_1$, where F_s and F_1 denote, respectively, the amplitudes of the force that acts on the support and the force that acts on the mass. If the support in the

Figure 1 Basic system consisting of mass connected to support via an isolator (a) excited by support motion (b) excited by force acting on mass.

second case is immobile, then the two transmissibilities are given by the same expression.* For the case where the isolator is undamped (i.e., where it dissipates no energy), this expression is

$$T = \frac{1}{|(f/f_n)^2 - 1|} \quad (1)$$

where the subscripts on T have been discarded. The symbol f denotes the excitation frequency and f_n denotes the natural frequency the isolator-mass system.

The natural frequency obeys

$$f_n = \frac{1}{2\pi} \sqrt{\frac{k}{m}} = \frac{1}{2\pi} \sqrt{\frac{g}{X_{st}}} \approx \frac{15.76}{\sqrt{X_{st}(\text{mm})}} \approx \frac{3.13}{\sqrt{X_{st}(\text{in.})}} \quad (2)$$

where k denotes the stiffness or *spring constant* of the isolator (the ratio of the force applied to the isolator to its deflection), g represents the acceleration of gravity, and X_{st} represents the *static deflection* of the isolator—that is, its deflection due to the weight of mass m .

For the more general situation where the isolator incorporates damping characterized by the loss factor.† η the transmissibility obeys

$$T = \sqrt{\frac{1 + \eta^2}{[(f/f_n)^2 - 1]^2 + \eta^2}} \quad (3)$$

If the damping is viscous—that is, if the isolator produces a retarding force proportional to the velocity (with a constant of proportionality c , called the viscous damping coefficient)—then the loss factor is $\eta = 2\pi f c / k = 2\zeta(f/f_n)$. Here $\zeta = c/c_c$ denotes the so-called damping ratio, where c_c is the critical viscous damping coefficient.‡

Figure 2 shows how the transmissibility T varies with the frequency ratio f/f_n for several values of the loss factor and several values of the damping ratio. In all cases T is greater than 1 for frequency ratios less than $\sqrt{2}$ —thus, at such low-frequency ratios the items that are to be protected are subjected to greater forces or motions than they would experience without any isolation. Protection of these items, corresponding to transmissibility values of less than unity, results only in the *isolation region*—that is, at frequency ratios that exceed $\sqrt{2}$ —and greater protection (smaller transmissibility) is obtained at higher frequency ratios. Thus, to obtain good isolation in the presence of a disturbance at a given excitation frequency f one needs to make the natural frequency f_n much smaller than f .

*Equality of the force and motion transmissibilities is a consequence of the reciprocity principle and holds between any two points of any mathematically linear system, including systems consisting of many masses, springs, and dampers.

†See Chapter 60 for definition and discussion of loss factor.

‡See Chapter 60 for information on measures of damping and their interrelation.

The effect of damping on transmissibility is also evident in Fig. 2. In the isolation region (i.e., where $f/f_n > \sqrt{2}$) greater damping results in greater transmissibility (and thus in poorer isolation). However, this deleterious effect is significant only in the presence of considerable viscous damping; it is insignificant in the presence of even rather high damping that is characterized by frequency-independent loss factors. Because the damping of most practical conventional isolators is relatively small and characterized by frequency-independent loss factors, their performance in the isolation range is not significantly affected by damping and the transmissibility may be approximated by Eq. (1), which reduces to as $T \approx (f_n/f)^2$ for large frequency ratios.

However, damping does have a significant effect on the transmissibility at and near resonance, where the excitation frequency matches the natural frequency. As Fig. 2 shows, greater damping results in reduced transmissibility in this frequency region. Therefore, greater damping often is desirable for isolating systems in which the excitation frequency can pass through resonance, for example, as a machine comes up to speed or coasts down.

To obtain the smallest transmissibility, one needs to make the frequency ratio f/f_n as large as possible. For given driving frequencies f this implies that one should make the natural frequency as small as one can—usually by choosing the smallest practical isolator stiffness k . The mass m generally is given. However, to reduce the natural frequency, one may consider adding an *inertia base* (a massive support) to the mass m so as to increase the total effective mass. But the loads that practical isolators can support are limited, so that addition of an inertia base may necessitate the use of a stiffer isolation arrangement, resulting in negation of at least some of the natural frequency reduction expected from the increased mass. Nevertheless, an added inertia base generally serves to reduce the vibrational excursions of an isolated item due to forces that act on it directly.

The *isolation I* is defined by $I = 1 - T$. Better isolation performance corresponds to greater values of I but to smaller values of transmissibility T . The isolation indicates the fraction of the disturbing force or motion that does not reach the item that is to be protected, whereas the transmissibility indicates the fraction of the disturbance that is transmitted to the protected item. Isolation is often expressed in percent. For example, a transmissibility of 0.0085 corresponds to an isolation of 0.9915 or of 99.15%.

2.1 Limitations of Basic Models and of Transmissibility; Isolation Effectiveness

The basic models assume the mass and support to be rigid, the isolator to be massless and mathematically linear (i.e., is, to deflect in proportion to the applied force), and all motions to occur along a straight line.

In cases where the isolator mass is small compared to the masses of the support and the isolated item, and where the frequencies of concern are low enough so

Figure 2 Transmissibility as function of ratio of forcing frequency to natural frequency of system consisting of mass supported on isolator modeled as damped spring, for various amounts of viscous damping (constant damping ratio ζ) and structural damping (constant loss factor η).

that no significant wave effects occur in the isolator,* an isolator does in effect act nearly as if it had no

mass. Although the force–deflection curves for some isolators, such as those made of rubber, typically are not straight lines—implying that the isolator is nonlinear—the isolator may in fact act linearly in the presence of small excursions. In that case its stiffness

*At frequencies at which standing-wave resonances occur in the isolator, the isolation performance may be considerably degraded. It usually is useful to relegate the domain where such resonances can occur to high frequencies (beyond the range of frequencies of concern) by selecting isolators with

small dimensions and of configurations and materials with high wave speeds.

may be taken as the slope of its force–deflection curve at the average deflection. However, a correction may be required for some isolators that incorporate elastomeric materials, in which the dynamic stiffness may differ significantly from the quasi-static stiffness obtained from the slope of the force–deflection curve. The effects of nonrigid isolated items and of motions that are not just along a straight line are addressed in later sections of this chapter.

The transmissibility, being the ratio of the transmitted force or motion to the exciting force or motion, does not account for changes in the excitation force or motion that may occur when a more flexible isolator is used. With a more flexible isolator the excitation is less restricted and may increase, defeating some of the isolation improvement one would expect from use of a more flexible isolator. In situations where the excitation can change significantly, depending on the resistance it encounters, the *isolation effectiveness* E is a better measure of isolation performance than the transmissibility. The isolation effectiveness is defined as

$$E = |V_{Rr}/V_R| = |F_{Rr}/F_R| \quad (4)$$

where V_{Rr} and F_{Rr} , respectively, denote the velocity and the force experienced by the isolated item if the isolator is replaced by a rigid connection (i.e., if no vibration isolator is used) and where V_R and F_R represent these quantities for the situation where the isolator is in place. The velocity ratio definition of E applies for the motion transmission case of Fig. 1a; the force ratio definition applies for the force transmission case of Fig. 1b.

3 TWO-STAGE ISOLATION

Two-stage isolation systems, as shown schematically in Fig. 3, can provide considerably greater high-frequency isolation than can the single-stage arrangement of Fig. 1. Unlike in the basic system of Fig. 1, where the mass m is connected to the supporting structure via a single isolator, in a two-stage system the mass m is connected to the supporting structure via two isolators (indicated as springs in Fig. 3) and an intermediate mass m_1 .

Figure 3 Schematic diagram of two-stage isolation system.

The system of Fig. 3 has two natural frequencies f_n given by

$$(f_n/f_1)^2 = C \pm \sqrt{C^2 - R^2} \\ 2C = R^2 + 1 + k_1/k_2 \quad R = f_2/f_1 \quad (5)$$

Here

$$f_1 = \frac{1}{2}\pi\sqrt{m(1/k_1 + 1/k_2)} \quad (6)$$

denotes the natural frequency of the system consisting of the mass m supported on the two springs in mechanical series, in the absence of the intermediate mass, and

$$f_2 = \frac{1}{2}\pi\sqrt{(k_1 + k_2)/m_1} \quad (7)$$

represents the natural frequency of the mass m_1 between the two springs for the situation where the mass m is held completely immobile. The symbols k_1 and k_2 represent the stiffnesses of the two springs, as shown in Fig. 3. The higher natural frequency f_n , which one obtains if one uses the plus sign before the square root in the first of Eq. (5), always is greater than the larger of f_1 and f_2 . The lower natural frequency, obtained if one uses the minus sign in the aforementioned equation, always is smaller than the smaller of f_1 and f_2 .

The (force and motion) transmissibility T of a two-stage system like that of Fig. 3 in the absence of damping* obeys

$$R^2/T = (f/f_1)^4 - [R^2 + k_1/k_2 + 1](f/f_1)^2 + R^2 \quad (8)$$

where f represents the excitation frequency and R is defined in Eq. (5). At high excitation frequencies the transmissibility obeys $T \approx (f_1 f_2 / f^2)^2$ and thus varies as $1/f^4$, implying very good isolation performance in this frequency range. However, this good performance occurs only at frequencies that are above the higher of the two natural frequencies of the system, so that it is desirable to make this natural frequency as small as possible. Because this higher natural frequency in practice often is f_2 , which depends on the intermediate mass m_1 , one generally should use the largest practical intermediate mass.

Figure 4 illustrates the aforementioned fact. One may observe that with a smaller intermediate mass (i.e., with a larger ratio of the primary mass m to the intermediate mass m_1), the rapid decrease of transmissibility with increasing frequency occurs at higher frequencies.

Where several items need to be isolated, it often is advantageous to support these on a common massive platform (sometimes called a “subbase” or “raft”), to isolate each item from the platform, and to isolate the platform from the supporting structure. In such

*The damping present in most practical isolation systems has relatively little effect on isolation performance. A more complicated expression applies in the presence of considerable damping.

Figure 4 Transmissibility of two-stage system of Fig. 3, with $k_1 = k_2$, for two ratios of primary to intermediate mass. The $m_1 = 0$ curve corresponds to a single-stage system.

an arrangement, the platform acts as a relatively large intermediate mass for isolation of each of the equipment items, resulting in efficient two-stage isolation performance with a comparatively small total weight penalty. The platform should be designed so that it exhibits no resonances of its own in the frequency range of concern. If such resonances cannot be avoided, the platform structure should be highly damped.

4 GENERAL SYSTEMS WITH ONE DEGREE OF FREEDOM

One may generalize the diagrams of Fig. 1 in terms of the diagram of Fig. 5, which shows a vibration source S connected to a "receiver" (an item or structure to be protected) R via an isolator. All motions and forces are assumed to act along the same line. Rather than representing the receiver as a rigid mass or an immovable support, one may consider a receiver whose velocity is proportional to the applied force (at each frequency). The ratio of the complex velocity* V_R of the receiver to the complex applied force F_R is defined as the receiver mobility $M_R = V_R/F_R$. The receiver mobility M_R is a frequency-dependent complex quantity that may be evaluated by applying a force at the receiver driving

Figure 5 General source connected to general receiver via an isolator.

point and measuring the magnitude and phase of the resulting velocity at that point.

Most vibration sources vibrate with lesser excursions if they act on stiffer structures and thus generate greater forces.[†] This behavior in its simplest terms is represented by a *general linear source* whose complex velocity V_0 is related to its complex force F_0 as $V_0 = V_{\text{free}} - M_S F_0$, where $M_S = V_{\text{free}}/F_{\text{blocked}}$ is a complex quantity, called the *source mobility*. V_{free} represents the (frequency-dependent) complex velocity with which the source vibrates if it generates zero force. F_{blocked} denotes the frequency-dependent complex force that the source produces if it is blocked,

*The complex velocity or velocity *phasor* contains magnitude and phase information. If $V = V_r + jV_i$, where $j = \sqrt{-1}$, then the magnitude of the velocity is given by $|V| = \sqrt{V_r^2 + V_i^2}$ and the phase is given by $\phi = \arctan(V_i/V_r)$. Corresponding expressions apply for the complex force.

[†]For example, a flexible sheet-metal mounting foot of an appliance or the armature of a small electrodynamic shaker may vibrate with considerable excursions if it is not connected to any structure, but tends to vibrate with lesser excursions if it is connected to structures or masses. The excursions will be less with connections to items with greater resistance to motion.

so that its velocity is zero. These quantities, and thus the source mobility, may be determined from measurements on a given source.

The mobility of a massless isolator* is defined as $M_I = (V_0 - V_R)/F_R$ in terms of the complex velocity difference across the isolator and the force applied to it, as indicated in Fig. 5. (With an isolator of zero mass, the forces on the two sides of the isolator are the same, $F_0 = F_R$.) The frequency-dependent mobility of a given isolator may readily be determined by measurement. The effectiveness obtained with an isolator whose mass is negligible obeys

$$E = \left| 1 + \frac{M_I}{M_S + M_R} \right| \quad (9)$$

In the special case where the source velocity remains unchanged, no matter how much force the source generates, $E = 1/T_{\text{motion}}$. In the special case where the source force output is constant, no matter what the source velocity is, $E = 1/T_{\text{force}}$. The effectiveness obtained with an isolator that has finite mass (i.e., if isolator mass effects are significant) is discussed in Refs. 1 and 2.

5 ISOLATION OF THREE-DIMENSIONAL MASSES

Unlike the basic model of Fig. 1, where the mass is constrained to move only along a line without rotating and where the system has only one natural frequency, an actual rigid mass can translate along three axes and rotate about three axes. An elastically supported rigid mass thus has six natural frequencies; a nonrigid mass has additional ones associated with its deformations. Obtaining good isolation here generally requires that all of the natural frequencies fall considerably below the excitation frequencies of concern. Analytical

expressions for the natural frequencies and responses of general rigid masses on general resilient supports are available[†] but are complex and provide little practical design guidance; their application generally requires repeated trial-and-error computation. The following paragraphs deal with special cases that provide some insight and design guidance.

5.1 Two-Dimensional (Planar) Coupled Rotational and Translational Vibrations

Figure 6 is a schematic diagram showing a mass that is supported on two isolators and restrained horizontally by two collinear isolators, with all isolators represented as springs. This diagram is a two-dimensional idealization of a three-dimensional mass that moves only parallel to a plane (the plane of the paper).[‡] The horizontal isolators shown in the figure may represent the stiffnesses of actual horizontally acting isolators or the stiffnesses in the horizontal direction of the supporting isolators, or a combination of the two.

In general, an up-and-down force applied at the center of gravity of the mass produces both an up-and-down displacement of the center of gravity and a rotational vibration of the mass, the latter resulting from the moment due to the isolator forces. Similarly, an oscillatory torque acting about the center of gravity produces both rotational and translational motions. The rotational and translational vibrations then are said to be coupled.

To obtain effective isolation, one needs to select the system parameters so that the system's greatest natural frequency falls as far as possible below the excitation frequency range. In the following discussion the isolators are considered to be undamped linear springs. The effect of practical amounts of damping generally is negligible for excitation frequencies that lie well above the greatest natural frequency.

Figure 6 Mass m with polar moment of inertia J supported on two vertically and two collinear horizontally acting isolators.

*The mobility of an isolator is the velocity analog to its compliance (the reciprocal of the stiffness). The mobility is equal to the velocity difference across the isolator, divided by the applied force; the compliance is equal to the compression of the isolator (the displacement difference across it), divided by the applied force. The complex mobility accounts for damping of the isolator, as well as for its stiffness.

[†]For example, See Ref. 3.

[‡]Such planar motions occur for excitations that act at the center of gravity and parallel to the plane and for arrays of isolators whose stiffnesses are distributed so that a force acting in the plane of the center of gravity induces no rotation out of the plane. The isolators indicated in Fig. 6 may be considered as representing the resultant stiffnesses of the isolator arrays.

5.2 Systems with Zero Horizontal Stiffness

In absence of finite horizontal stiffnesses and horizontal force components, the center of gravity of the mass of Fig.6 moves only in the vertical direction. The natural frequency f_v corresponding to vibration in the vertical direction without rotation—the so-called uncoupled vertical translational natural frequency—is given by

$$2\pi f_v = \sqrt{\frac{k_1 + k_2}{m}} \quad (10)$$

where k_1 and k_2 represent the spring constants of the vertically acting isolators and m denotes the mass. The natural frequency f_r corresponding to rotational vibrations without displacement of the center of gravity—the so-called uncoupled rotational frequency—is given by

$$2\pi f_r = \sqrt{(k_1 a_1^2 + k_2 a_2^2)/J} \quad (11)$$

where a_1 and a_2 are the horizontal distances from the vertically acting isolators to the center of gravity, as shown in Fig. 6, and where J denotes the mass' polar moment of inertia about an axis through the center of gravity and perpendicular to the plane of the paper. The uncoupled rotational natural frequency f_r may be greater or smaller than the uncoupled vertical translational natural frequency f_v .

The two natural frequencies of the system generally differ from the aforementioned uncoupled natural frequencies and are given by the two values obtained from the following relation (one for the plus and one for the minus sign preceding the square root):

$$\begin{aligned} f_n^2 &= f_a^2 \pm \sqrt{f_a^4 + f_v^2 f_r^2 U} \\ f_a^2 &= \frac{f_v^2 + f_r^2}{2} \\ U &= \frac{(a_1 + a_2)^2}{(1/k_1 + 1/k_2)(k_1 a_1^2 + k_2 a_2^2)} \end{aligned} \quad (12)$$

The larger of these two “coupled” natural frequencies is greater than both f_v and f_r ; the smaller of the two coupled natural frequencies is smaller than both f_v and f_r .

To provide good isolation in the general case, one needs to select the isolators and their locations so that the larger coupled natural frequency falls considerably below the excitation frequencies of concern. It often is most convenient to select the isolator stiffnesses and locations so that the forces produced by the isolators when the mass is deflected vertically without rotation produce zero net torque about the center of gravity. This may be accomplished by selecting the isolation system so that all vertically acting isolators have the same static deflection due to the weight they support

statically.* In this case vertical forces that act at the center of gravity or vertical motions of the support produce no rotational or “rocking” motions, and the natural frequencies of the system are the uncoupled natural frequencies discussed at the beginning of this section.

5.3 Systems with Finite Horizontal Stiffness

If the horizontally acting stiffnesses shown in Fig.6 are not negligible, then the system has three natural frequencies. For the case where the vertically acting isolators are selected and positioned so that they have the same static deflection, as discussed above, the vertical translational motion and the rotational motion are uncoupled and the natural frequency for vertical vibration is the aforementioned f_v . The other two natural frequencies, relating to coupled in-plane rotation and horizontal translation then are given by

$$(f_n/f_v)^2 = N \pm \sqrt{N^2 - PW} \quad (13)$$

where

$$\begin{aligned} 2N &= P \left(1 + \frac{b^2}{r^2} \right) + W \\ P &= \frac{h_1 + h_2}{k_1 + k_2} \quad W = \frac{k_1 a_1^2 + k_2 a_2^2}{r^2(k_1 + k_2)} \end{aligned} \quad (14)$$

The dimensions a_1, a_2 , and b are indicated in the figure, h_1 and h_2 denote the horizontal stiffnesses, and $r = \sqrt{J/m}$ represents the radius of gyration of the mass about an axis through its center of gravity and perpendicular to the plane of the paper. For a rectangular mass of uniform density with height and length H and L , $r = \sqrt{(H^2 + L^2)/12}$.

6 PRACTICAL ISOLATORS

A great many different isolators of numerous sizes and load capacities are available commercially. Details typically may be found in suppliers' catalogs.

Most isolators incorporate metallic and/or elastomeric resilient elements. Metallic resilient elements most often are in the form of coil springs but may also be in the form of leaf springs, rings, or Belleville washers, among others. Coil springs of metal predominantly are used in compression because their use in tension tends to require end supports that induce stress concentrations and result in reduced fatigue life. Many coil spring isolator assemblies make use of parallel and/or series arrangements of springs in suitable housings and may include damping devices (such as viscoelastic elements, wire mesh sleeves, or other friction devices), snubbers to limit excursions due to large disturbances such as earthquakes, and in-series elastomeric pads

*It is assumed that the isolators are linear—that is, that each isolator's deflection is proportional to the force that acts on it. If the isolators are selected so that they have the same unloaded height, as well as the same static deflection, then the isolated mass will be level in its equilibrium position.

for enhanced damping and high-frequency isolation. Springs need to be selected to be laterally stable. Spring systems in housing need to be installed with care to avoid binding between the housing elements and between these and the springs.

Some commercial metallic isolators that do not employ conventional coil springs make use of pads or woven assemblies of wire mesh to provide both resilience and damping. Others use arrangements of coils or loops of wire rope to serve as a damped spring.

Many commercially available isolators employ elements of elastomeric materials (e.g., rubber or neoprene) that are bonded to support plates or sleeves that incorporate convenient means for fastening of these isolators to other components. The isolators may be configured so that the elastomeric elements work in shear, in compression, in torsion, or in a combination of these. There are also available a variety of elastomeric gaskets, grommets, sleeves, and washers, which are intended to be used in conjunction with conventional bolts or similar fasteners.

Pads of elastomeric material or of such other resilient materials as cork, felt, fiberglass, or metal mesh are often used as isolators by themselves. Such pads often are convenient and relatively inexpensive. Their areas can be selected to support the required loads and their thicknesses can be chosen to provide the desired resilience within practical limits.

In the selection of pads of a solid elastomeric material (in contrast to pads made of foamed material or of material with ribs or voids), one needs to take into account that such a pad's stiffness depends not only on its area and thickness but also on its shape and constraints. Because elastomeric materials are nearly incompressible, a pad of such a material exhibits greater stiffness if bulging of its edges is restricted to a greater degree. The *shape factor* of a pad is defined as the ratio of its loaded area to the total area that is free to bulge. The greater the shape factor, the greater the pad's stiffness. The stiffness is also affected by how easily the loaded surfaces of a pad can slip relative to the adjacent surfaces; the more this slipping is restrained, the greater is the stiffness of the pad. Isolation pads are often supplied with their top and bottom load-carrying surfaces bonded to thin metal plates or the like, not only to eliminate stiffness uncertainties associated with uncontrolled slippage but also to reduce creeping of the material out of the loaded areas.

To avoid the complications associated with the shape factor in the selection of elastomeric pads, commercial isolation pad configurations are available that incorporate a multitude of closely spaced openings into which the material can bulge, thus providing practically the same shape factor for any pad area. Arrays of holes, ribs, dimples, or the like typically serve this purpose. If stacks of such pads are used, metal sheets or the like generally are placed between adjacent load-carrying surfaces to avoid having protrusions on one pad extending into openings of an adjacent one.

Pneumatic or *air-spring* isolators obtain their resilience primarily from the compressibility of confined volumes of air. They may take the form of air-filled cylinders or rings of rubber or plastic, or they may consist essentially of pistons in rigid air-filled cylinders. Highly resilient air springs are available that can support large loads and provide natural frequencies as low as 1 to 2 Hz. Such isolation performance generally cannot readily be obtained with any of the aforementioned isolation arrangements that employ only solid materials. Piston-type air springs usually provide isolation primarily in the vertical direction and often need to be supplemented with other devices to enhance isolation in the horizontal direction. Some commercial air-spring systems can be obtained with leveling controls that keep an isolated platform in a given static position as the load on the platform changes or moves about.

The stiffness of a piston-type air spring is proportional to pA^2/V , where p denotes the absolute pressure of the air in the cylinder, A the piston surface area, and V the cylinder volume. The product $(p - p_a)A$, where p_a denotes the ambient air pressure, is equal to the load carried atop the piston. Thus, the pressure p may be adjusted to support a given load. If p is much greater than p_a , the stiffness of the air spring is proportional to the load, and the natural frequency one obtains with the air spring is independent of the load. This makes air springs particularly useful for applications in which the loads are variable or not fully predictable. The spring stiffness may be made small by use of a large volume; this is often achieved by means of auxiliary tanks that communicate with the cylinder via piping. In some instances flow restrictions are included in this piping to provide damping.

Pendulum arrangements often are convenient for isolation of vibrations in the horizontal directions. The natural frequency of a pendulum of length L is given by

$$f_n = \frac{1}{2\pi} \sqrt{\frac{g}{L}} \approx \frac{15.76}{\sqrt{L(\text{mm})}} \approx \frac{3.13}{\sqrt{L(\text{in.})}} \quad (15)$$

where g denotes the acceleration of gravity. Some commercial isolation systems combine pendulum elements for horizontal isolation with spring elements for vertical isolation.

Systems in which spring action is provided by magnetic or electrostatic means also have been investigated and used for some special applications, as have other systems where levitation is provided by streams or thin films of fluids. Active isolation systems recently have attracted considerable attention. Such systems in essence are dynamic control systems in which the vibration of the item that is to be protected is sensed by a suitable transducer whose appropriately processed output is used to drive an actuator so as to reduce the item's vibrations. Active systems require an external source of energy and tend to be rather complex, but they can provide better isolation than passive systems (i.e., systems that do not require an external source

of energy), notably in the presence of disturbances at very low frequencies.

CHAPTER 60

DAMPING OF STRUCTURES AND USE OF DAMPING MATERIALS*

Eric E. Ungar
Acentech Incorporated
Cambridge, Massachusetts

1 INTRODUCTION

Damping—the dissipation of energy in a vibration—has a significant effect only on vibrational motion in which energy loss plays a major role. Increased damping increases the rate of decay of free (i.e., unforced) vibrations and reduces the amplitudes of steady vibrations at resonances, including vibrations due to random excitation. Damping reduces the rate of buildup of vibrations at resonances and limits the amplitudes of “self-excited” vibrations—that is, of vibrations in which a vibrating structure accepts energy from a steady source, such as flow of a fluid. Damping also increases the rate of decay of freely propagating waves and limits the buildup of forced wave motions. Furthermore, damping reduces the response of structures to sound and the transmission of sound through structures at frequencies above their coincidence frequencies.

Increased damping tends to result in the reduction of vibratory stresses and thus in increased fatigue life. It also leads to the reduction of noise associated with impacts, as well as to reduced transmission of energy in waves propagating along a structure. Damping increases the impedances of structures at their resonances and thus at these resonances may improve the effectiveness of vibration isolation.

Devices and materials that enhance the damping of structures are widely used in automobiles, ships, aerospace vehicles, and in industrial and consumer equipment. In many applications, *damping materials*—materials that can dissipate relatively large amounts of energy (typically plastics and elastomers)—are combined judiciously with conventional structural elements.

2 DAMPING MECHANISMS

Anything that results in loss of mechanical energy from a vibrating structure contributes to the damping of that structure. This includes friction between components, interaction of a structural component with adjacent fluids (including sound radiation into these fluids, which may play an important role in structures that are immersed in liquids), electromagnetic effects, transmission of energy to contiguous structures, and *mechanical hysteresis*—dissipation (conversion into

heat) of energy within the materials of the structure. This chapter focuses primarily on the damping of structures due to the energy dissipation in materials and in combinations of materials.

3 MEASURES AND MEASUREMENT OF DAMPING

The damping of a structure may be determined from the rates of the decay of vibrations of its modes, from the behavior of its structural modes[†] at and near their resonances, from direct measurement of energy loss in steady-state vibration, or from evaluation of the spatial rate of decay of freely propagating waves.

The dynamic behavior of a structural mode may be considered conveniently in terms of a simple mass–spring–damper system that has the same natural frequency as the mode and a representative *modal mass* m and a *modal stiffness* k . Because the assumption of *viscous damping*—that is, of dampers that provide a retarding force that is proportional to the velocity of the mass—leads to easily solved linear differential equations for the system motions, viscously damped systems have been studied extensively. Even though viscous damping is encountered relatively rarely in practice, results obtained for viscously damped systems provide some useful insights.

In a spring–mass–damper system with viscous damping the amplitude in a freely decaying motion varies with time t as $e^{-\zeta\omega_n t}$, where $\omega_n = \sqrt{k/m}$ represents the undamped radian natural frequency of the system. The damping ratio $\zeta = c/c_c$ relates the viscous damping coefficient c (the constant of proportionality of the retarding force to the velocity) to the so-called critical damping coefficient[‡] $c_c = 2\sqrt{km} = 2m\omega_n$. One may determine the damping ratio from the magnitudes of successive relative maxima in the record[§] of a freely decaying vibration by use of

[†]In general, different modes of a structure may exhibit different amounts of damping.

[‡]If a system with a viscous damping coefficient c that is smaller than the critical damping coefficient is displaced from equilibrium and released, it oscillates about its equilibrium position with decreasing amplitude. If a system with a viscous damping coefficient that is greater than the critical damping coefficient is similarly displaced and released, it drifts toward its equilibrium position without oscillating past it.

[§]The record may be of any quantity proportional to the displacement, velocity, or acceleration.

*This chapter is essentially a distillation of Ref. 1, where more details may be found.

the relation

$$\zeta = \frac{\delta}{2\pi} = \frac{1}{2\pi N} \ln \frac{X_i}{X_{i+N}} \quad (1)$$

where X_i denotes the magnitude of a given maximum and X_{i+N} denotes the magnitude of the N th maximum after the given one. The symbol δ represents a time-honored measure of damping, called the *logarithmic decrement*.

One may also evaluate the damping of a mode (or of the mass–spring–damper system that represents it) by subjecting it to sinusoidal forcing of constant amplitude F and observing its steady-state responses. The amplification at a given excitation frequency ω is defined as the ratio of the displacement amplitude $X(\omega)$ at that frequency to the quasi-static displacement amplitude X_{st} (the displacement amplitude for $\omega \approx 0$). The amplification at resonance, Q , is defined as $Q = X(\omega_n)/X_{st}$, corresponding to the situation where the forcing frequency ω is equal to the natural frequency ω_n . In the presence of viscous damping, Q is related to the damping ratio by $\zeta = \frac{1}{2}Q$. One also may evaluate the damping from the relative bandwidth

$$b = (\omega_2 - \omega_1)/\omega_n = 1/Q \quad (2)$$

where ω_1 and ω_2 denote the two *half-power-point frequencies*—that is, the two excitation frequencies ($\omega_1 < \omega_n$ and $\omega_2 > \omega_n$) at which the amplification is equal to $Q/\sqrt{2}$. This equation is exact for the case of viscous damping, but it is also often used to quantify the damping in other situations.

The foregoing paragraphs deal with the special case of viscous damping. In the general case it is advantageous to use measures of damping that are based on energy considerations. One such measure is the damping capacity ψ , which is defined as the ratio of the energy D that is dissipated per cycle in a steady vibration to the time-average total energy W present in the vibrating system. (In lightly damped systems the total energy varies little with time and may be taken as constant for all practical purposes.) The most widely used measure of damping, the loss factor η , is defined analogously to the damping capacity, but in terms of the energy dissipated per radian:

$$\eta = \psi/2\pi = D/2\pi W \quad (3)$$

If the damping is small, the loss factor may be related to an equivalent viscous damping ratio via $\eta \approx 2\zeta$ —in other words, a viscously damped system with damping ratio ζ here dissipates essentially the same fractional amount of energy per cycle as a system with nonviscous damping that is characterized by a loss factor η .

The loss factor of a system that is vibrating in the steady state may be determined from direct measurement of the average energy that is dissipated per unit time, which is equal to the average energy

that is supplied to the system per unit time. The latter may be evaluated from measurement of the force and velocity at the point(s) where the system is driven. The energy stored in the system may be determined from its mass and mean-square velocity.

In analyzing the response of a system to sinusoidal excitation, it often is convenient to use complex or “phasor” notation. In terms of this notation the time-dependent variation of a variable $x(t) = X \cos(\omega t + \phi)$ is expressed as $x(t) = \text{Re}[\bar{X}e^{j\omega t}]$, where $j = \sqrt{-1}$ and $\bar{X} = X_r + jX_i$ is a complex quantity consisting of real and imaginary components. This complex quantity contains information about both the magnitude (amplitude) and the phase ϕ of the variable. If one uses phasor notation, one may represent the stiffness and damping of a system together in terms of a complex stiffness

$$\bar{k} = k + jk_i = k(1 + j\eta) \quad (4)$$

where $\eta = k_i/k$ corresponds to the previously discussed loss factor.*

One may represent the frequency-dependent behavior of realistic systems by taking the loss factor to vary with frequency to correspond to empirically measured data. The damping of metals and some other widely used structural materials often can be described by a loss factor that is practically independent of frequency, at least in limited frequency ranges of practical interest. A frequency-dependent loss factor also may be used to represent various mathematical damping models. For example, to a viscously damped system there corresponds the loss factor $\eta = c\omega/k$, which is proportional to frequency.

The various measures of damping are interrelated as follows: $\eta = \psi/2\pi = k_i/k$ holds in general and at all frequencies, but $\eta = 1/Q$ holds only at resonance. For small damping of any type, $\eta \approx b$. For viscous damping, $\eta = 2\zeta = b = \delta/\pi \approx \Delta_\lambda/13.6$. The symbol Δ_λ represents the spatial decay rate (in decibels per wavelength), defined as the reduction of vibration level† per wavelength in freely propagating waves.

4 DAMPING BEHAVIOR OF MATERIALS

The dynamic behavior of a material can be described most readily in terms of its complex modulus of elasticity, which may be determined from measurement of

*One may also determine the damping of a mode from a plot of the imaginary versus the real part of the mobility, obtained from measurements over a range of frequencies that includes the resonance. (Mobility is defined as the ratio of the velocity phasor to the phasor of the exciting force.) The aforementioned plot is in the shape of a circle whose diameter is equal to $Q = 1/\eta = 1/2\zeta$. Commercial software for experimental modal analysis often uses this approach for evaluation of damping.

†The vibration level L of a vibration variable $x(t)$ is defined in analogy to the sound pressure level in acoustics as $L = 10 \log_{10}[x^2(t)/x_{\text{ref}}^2]$, where x_{ref} represents an arbitrary constant reference value in the same units as the time-dependent variable.

the complex stiffness of a material sample. In analogy to the complex stiffness, as in Eq. (4), the complex modulus of elasticity is defined as

$$\bar{E} = E + jE_i = E(1 + j\beta) \quad (5)$$

The real part, E , is associated with strain energy storage and corresponds to the well-known modulus of strength of materials and elasticity theory; the imaginary part, E_i , is called the *loss modulus* and is associated with energy dissipation. The loss factor related to the modulus of elasticity obeys $\beta = E_i/E$. Completely analogous definitions apply for the shear modulus. For most materials of engineering interest the loss factor associated with the modulus of elasticity is for all practical purposes equal to the loss factor associated with the shear modulus.*

The loss factor of a material in general may vary with frequency, temperature, strain amplitude, steady loading present in conjunction with a vibration, and previous cyclic loading. In most metals, the damping is relatively independent of frequency, of temperatures that are well below the melting point, and of strain amplitudes that are considerably below those at which structural fatigue tends to be a significant concern. Thus, for many applications the loss factor of a metal may be taken as essentially constant. On the other hand, the loss factors of plastics and rubbery materials generally vary markedly with frequency and temperature, as discussed below, but often are relatively independent of strain amplitude up to strains of the order of unity.

Figure 1 indicates typical ranges of the loss factors reported for materials at small strains, near room temperature, and at audio and lower frequencies. The range indicated for plastics and rubbers is large because it encompasses many materials and because the properties of individual materials of this type may vary considerably with frequency and temperature. On the whole, the loss factors of high-strength materials, particularly of metals, tend to be much smaller than those of plastics and rubbers, which are of lower strength.

Plastics and rubbers are called *viscoelastic materials* because they exhibit both energy dissipative (viscous) and energy storage (elastic) behaviors. The storage and loss moduli, as well as the loss factors, of these materials typically vary considerably with frequency and temperature. At the conditions at which these materials are used most often, their shear moduli are very nearly equal to one-third of the corresponding moduli of elasticity, and the loss factors in shear are very nearly equal to those in tension and compression. The properties of a sample of a given material are strongly dependent on the sample's composition and processing (e.g., on its chemical constituents and their molecular weight distribution and

cross-linking, and on its filler and plasticizer content), so that nominally similar samples may exhibit significantly different dynamic properties. The effects of preloading and strain amplitude on polymeric materials are discussed in Ref. 2.

Figure 2 illustrates how the (real) shear modulus and loss factor of a typical plastic material consisting of a single polymer varies with frequency and temperature.[†] At a given frequency, the modulus is relatively small at low temperatures and small at high temperatures, whereas the loss factor is relatively small at both low and at high temperatures and tends to exhibit a maximum in the region where the modulus changes most rapidly with temperature. At low temperatures the material is said to be in the glassy region because it tends to be hard and brittle; at high temperatures it is said to be in the rubbery region. The dividing point between these two regimes occurs at the so-called *glass transition temperature*, at which the rate of change of the modulus with temperature is greatest.

The material properties change with increases in frequency at constant temperature somewhat like they do with decreases in temperature at constant frequency. At a given temperature the modulus is relatively small at low frequencies and increases with increasing frequency, whereas the loss factor is relatively small at both low and high frequencies, with a maximum at intermediate frequencies. It has been observed that a given change in temperature has the same effect on the modulus and loss factor as does an appropriate shift in frequency. This *temperature-frequency equivalence* makes it possible to represent the behavior of many viscoelastic materials in terms of single curves for the modulus and loss factor as functions of a *reduced frequency* $f_R = f\alpha_T$, where f denotes the actual frequency and α_T is a *shift factor* that depends on the temperature. This shift factor may be given via an equation or separate plot, or—most conveniently—via a nomogram that is superposed on the data plot as shown in Fig. 3. (Use of this nomogram is illustrated in the figure.) Plots of this type have come into wide use and have become standardized. Shift factor relations are discussed in Ref. 2 and 3.

Table 1 presents some key parameter values for several commercial viscoelastic materials intended for high-damping applications.[‡] The data in the table are useful for preliminary material comparison and selection for specific applications. In general it is advisable to select specific materials on the basis of complete data for the candidate materials. Such data

*Approximate equality of the loss factors implies that the imaginary part of Poisson's ratio is negligible.

[†]The dynamic behavior of a material consisting of more than one polymer tends to be a blend of the behaviors of its components. The plots corresponding to Fig. 2 then exhibit more complex curvatures, and the loss factor curves may exhibit more than one peak.

[‡]Suppliers often change the designations of their materials. Some of the listed materials may be available with different designations, some may no longer be available.

Figure 1 Typical ranges of material loss factors at small strains and audio frequencies, near room temperature.

typically are available from knowledgeable material suppliers.

5 DAMPING OF STRUCTURES WITH VISCOELASTIC COMPONENTS

Because most structural materials are strong and have little damping, whereas most viscoelastic materials have considerable damping and relatively little strength, configurations are of interest that combine the strength of the former and the damping of the latter types of materials.

The loss factor η_{comb} of any multicomponent structure that vibrates in a manner in which all components deflect essentially in phase obeys $\eta_{\text{comb}} = \sum \eta_i W_i / W_{\text{tot}}$, where η_i denotes the loss factor of the i th component, W_i denotes the energy stored in that component, and W_{tot} denotes the total energy stored in all of the components. The sum extends over all of the components. The general equation reduces to

$\eta_{\text{comb}} = \eta_a W_a / W_{\text{tot}}$ if the structure includes only one component, identified by the subscript a , that has nonzero damping. This equation indicates that (1) the loss factor of the composite cannot be greater than the loss factor of the component with finite damping, and (2) if the composite is to have a considerable loss factor, not only does the loss factor η_a of the damped component have to be large, but that component also has to share in the total energy to a considerable extent.

5.1 Beams with Single Viscoelastic Components

In the bending of uniform beams with cross sections of the types illustrated by Fig. 4, where an insert or adhered layer of a viscoelastic material is added to a primary structure that has little inherent damping, energy dissipation is associated primarily with extension and compression of the viscoelastic elements. If

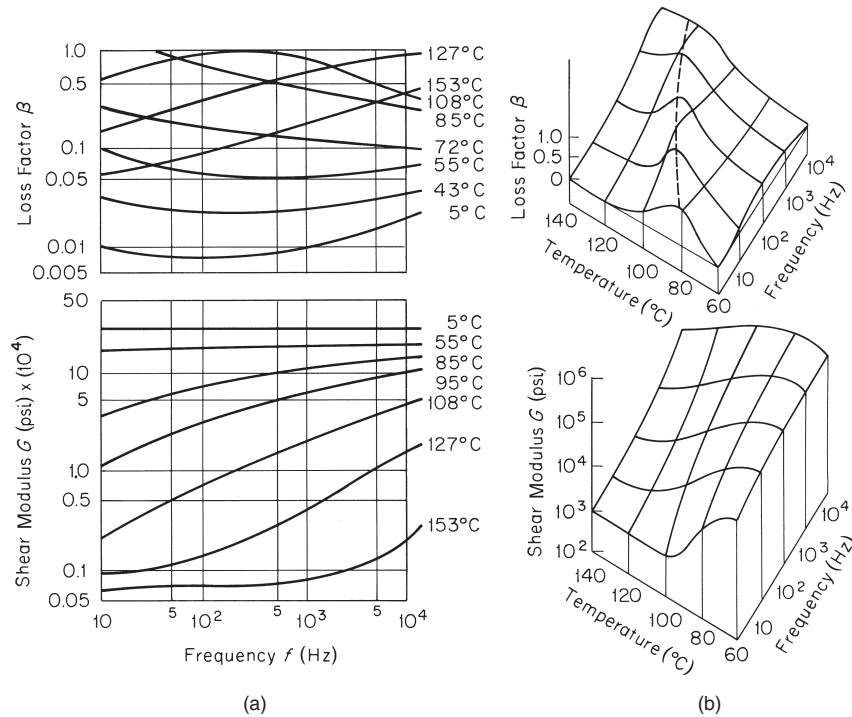

Figure 2 Dependence of shear modulus and loss factor of a polyester plastic on frequency and temperature: (a) functions of frequency at constant temperatures and (b) three-dimensional plots on temperature log-frequency axes.

Figure 3 Reduced frequency plot of modulus of elasticity E and loss factor β of a silicone potting compound. Points indicate measured data to which curves were fitted. Nomograph facilitates determination of reduced frequency f_R for given frequency and temperature as illustrated by dashed lines. For $f = 15$ Hz and $T = 20^\circ\text{C}$ one finds $f_R = 5 \times 10^3$ Hz, $E = 3.8 \times 10^6$ N/m², $\beta = 0.36$.

^aTabulated values are approximate, taken from curves in Ref. 2.

β_{\max} = Maximum loss factor of material.

Temperatures (°F) at which maximum loss factor occurs at the indicated frequencies may be converted to °C by use of the formula °C = (5/9) (°F - 32).

To obtain elastic moduli in N/m² multiply tabulated values by 7×10^6 . Shear modulus values are one third of elastic modulus values.

E_{\max} = Maximum value of real modulus of elasticity, applies at low temperatures and/or high frequencies.

E_{\min} = Minimum value of real modulus of elasticity, applies at high temperatures and/or low frequencies.

E_{trans} = Value of real modulus of elasticity in region where maximum loss factor occurs.

$E_{i,\max}$ = Value of imaginary modulus of elasticity in region where maximum loss factor occurs.

Figure 4 Cross sections of beams with viscoelastic inserts or added layers. Viscoelastic material is shown shaded, structural material unshaded. H_{12} represents distance between neutral axes of components.

no slippage occurs at the interfaces and if the deformation shape of the beam is sinusoidal,* then the loss factor contribution η of the viscoelastic element[†] is related to the loss factor β_2 of the viscoelastic material

by

$$\eta = \beta_2 \left[1 + \frac{k^2(1 + \beta_2^2) + (r_1/H_{12})^2\gamma}{k[1 + (r_2/H_{12})^2\gamma]} \right]^{-1} \approx \frac{\beta_2 E_2 I_T}{E_1 I_1} \quad (6)$$

where $\gamma = (1 + k)^2 + (\beta_2 k)^2$ and H_{12} denotes the distance between the neutral axes of the elastic and viscoelastic components, as indicated in Fig. 4. Here and subsequently the subscript 1 refers to the structural (undamped) component and subscript 2 to the viscoelastic component. Also, $k = K_2/K_1$, where $K_n = E_n A_n$ denotes the extensional stiffness of component n , expressed in terms of its (real) modulus of elasticity E_n and cross-sectional area A_n . The radius of gyration of the area A_n is represented by $r_n =$

*The equations presented here also hold approximately if the deformation shape is not sinusoidal. They hold well for the higher modes of a beam, regardless of the end conditions, because the deformation shape associated with such a mode is essentially sinusoidal, except near the ends.

[†]The loss factor contribution of the viscoelastic element is equal to the loss factor of the composite beam if the loss factor of the other element is negligible.

Figure 5 Dependence of loss factor η of plate with adhered viscoelastic layer on relative thickness and relative modulus of layer, for material loss factor $\beta_2^2 \ll 1$.

$\sqrt{I_n/A_n}$, with I_n denoting the centroidal moment of inertia of that area.

The last, more approximate, form of equation (6) pertains to the often-encountered case where the structural component's extensional stiffness is much greater than that of the viscoelastic component, with $I_T = I_2 + H_{12}^2 A_2$ and $E_2 I_T \ll E_1 I_1$. Note that the dominant viscoelastic material property is the product $\beta_2 E_2$, which is the loss modulus (the imaginary part of the complex modulus) of the material. Thus, an efficient damping material here needs to have both a large loss factor and a large modulus of elasticity.

5.2 Plates with Viscoelastic Coatings

A strip of a plate with a viscoelastic coating may be considered as a special case of a beam with a single viscoelastic component, where the beam and the viscoelastic element have rectangular cross

sections (see insert of Fig. 5).^{*} Then Eq. (6) and the foregoing relations apply with $r_n = H_n/\sqrt{I_2}$ and $H_{12} = (H_1 + H_2)/2$, where H_n denotes the thickness of the component identified by the subscript, with subscripts 1 and 2 referring to the elastic and the viscoelastic layers, respectively. A plot of η/β_2 for the often-encountered situation where $\beta_2^2 \ll 1$ appears in Fig. 5.

For small relative thicknesses $h_2 = H_2/H_1$ —that is, where the curves of Fig. 5 are nearly straight—the loss factor of a coated plate obeys

$$\eta \approx \frac{\beta_2 E_2}{E_1} h_2 (3 + 6h_2 + 4h_2^2) \approx 3 \frac{\beta_2 E_2}{E_1} \frac{H_2}{H_1} \quad (7)$$

and is essentially proportional to the thickness H_2 of the viscoelastic layer. For very large relative

^{*}A viscoelastic layer without a “constraining layer” atop it is often called a *free* or *unconstrained* damping treatment.

Figure 6 Cross sections of composite beams consisting of two structural components (unshaded) joined via a viscoelastic component (shaded). H_{13} denotes distance between neutral axes of structural components.

thicknesses, the loss factor of a coated plate approaches that of the viscoelastic coating layer itself. Because the loss factor of a coated plate is proportional to the loss modulus (the product $\beta_2 E_2$) of the damping material, an effective damping material needs to have both a high loss factor and a large modulus of elasticity.

If two viscoelastic layers are applied to a plate, one layer on each side, and if the extensional stiffness of each is considerably less than that of the structural layer (i.e., if $E_2 H_2 \ll E_1 H_1$), then the loss factor of the coated plate may be taken as the sum of the loss factors contributed by the individual layers, with each layer's contribution calculated as if the other layer were absent. A more complex relation applies in the case where the layers have large relative extensional stiffnesses; in this case the total damping contribution is less than the sum of the separately calculated contributions.

5.3 Three-Component Beams with Viscoelastic Interlayers

Figure 6 illustrates the cross sections of some beams, each consisting of two structural (nonviscoelastic) components interconnected via a relatively thin viscoelastic component. As uniform beams of this type vibrate in bending, energy dissipation occurs predominantly due to shear in the viscoelastic components.

The damping behavior of such a beam vibrating in bending with an essentially sinusoidal deflection shape may be described with the aid of a *structural parameter* Y and a *shear parameter* X , defined by

$$\frac{1}{Y} = \frac{E_1 I_1 + E_3 I_3}{H_{13}^2} S \quad X = \left(\frac{\lambda}{2\pi} \right)^2 \frac{G_2 b}{H_2} S \quad (8)$$

Here $S = 1/E_1 A_1 + 1/E_3 A_3$. Subscripts 1 and 3 refer to the structural components and 2 refers to the viscoelastic component. E_n , A_n , and I_n represent, respectively, the modulus of elasticity, cross-sectional area, and cross-sectional moment of inertia (about its own centroid) of component n . H_{13} denotes the distance between the neutral axes of the two structural components (as indicated in Fig. 6) and G_2 denotes the shear modulus (real part) of the viscoelastic material. H_2 denotes the average thickness of the viscoelastic

layer and b represents the length of that layer's trace in the plane of the cross section of the beam.

The term λ denotes the bending wavelength, which for a spatially sinusoidal beam deflection obeys $(\lambda/2\pi)^2 = \sqrt{B/\mu}/\omega$, where B represents the magnitude of the (complex) flexural rigidity and μ the mass per unit length of the composite beam. The complex flexural rigidity of a three-component beam obeys

$$\bar{B} = (E_1 I_1 + E_3 I_3) \left(1 + \frac{\bar{X} Y}{1 + \bar{X}} \right)$$

where $\bar{X} = X(1 + j\beta_2)$.

The shear parameter is a measure of how well the viscoelastic component couples the flexural motions of the two structural components. For small values of X , B is equal to the sum of the flexural rigidities of the two structural components—that is, to the flexural rigidity that the beam would exhibit if the two components were not interconnected. For large values of X , on the other hand, B is equal to $1 + Y$ times the foregoing value and corresponds to the flexural rigidity the beam would exhibit if the two structural components were rigidly interconnected.

The structural parameter Y depends only on the geometry and on the moduli of elasticity of the two structural components, whereas the shear parameter X depends also on the properties of the viscoelastic component and on the wavelength of the beam deflection.

A plot of the loss factor η of a composite beam for given values of Y and of β_2 versus the shear parameter X has the shape of an inverted parabola, as shown in Fig. 7. Each such plot exhibits a maximum loss factor

$$\eta_{\max} = \frac{\beta_2 Y}{2 + Y + 2/X_{\text{opt}}} \quad (9)$$

at an optimum value of X , which obeys

$$X_{\text{opt}} = [(1 + Y)(1 + \beta_2^2)]^{-1/2} \quad (10)$$

The equation

$$\frac{\eta}{\eta_{\max}} = \frac{2(1 + N)R}{1 + 2NR + R^2} \quad (11)$$

Figure 7 Dependence of loss factor η of three-component structures with various structural parameters Y and damping material loss factors β_2 on the shear parameter X .

where $R = X/X_{\text{opt}}$ and $N = (1 + Y/2)X_{\text{opt}}$, indicates the dependence of the loss factor on X , Y , and β_2 and may be used to calculate the loss factor of a given three-component beam at a given frequency. It also is useful for determining how close a given beam's damping comes to the maximum that can be achieved with a given configuration and viscoelastic material.

If one knows the properties of the viscoelastic material under the conditions of interest and the bending wavelength λ of concern, one may readily determine X from its definition, Eq. (6). Otherwise, one needs to determine X from a process that takes account of the dependence of λ on B and of the dependence of B on X . A suitable approach consists of an iterative process that consists of (1) calculation of X_{opt} , (2) evaluation of the corresponding value of B , (3) calculation of the resulting value of λ , (4) using this value of λ to determine a new value of X , and (5) repeating these steps, beginning with the newly determined value of X , until the final and the initial values of X match to the desired degree. This process usually converges rapidly.

5.3.1 Design Considerations The maximum loss factor η_{max} that can be achieved in a composite beam by use of a damping material with a given loss factor β_2 increases monotonically with the structural parameter Y . Thus, to obtain a highly damped beam, one should select a configuration with as large a structural parameter as practical. Figure 8 presents the expressions for the structural parameters for some typical composite beam configurations.* Once one has selected Y and a damping material, one should make the expected loss factor equal to the greatest possible value, η_{max} . Since the maximum loss factor occurs at the optimum shear parameter X_{opt} , the value of which can readily be determined from Y and β_2 , one should adjust the value of X at the frequency of interest so that it equals the calculated value of X_{opt} . For

*Greater values of Y than those shown may be obtained by insertion of a shear-stiff, extensionally soft *spacer* layer (e.g., of a honeycomb material) between the viscoelastic element and one or both structural elements. This has the effect of increasing H_{13} .

Figure 8 Expressions for structural parameter Y for various three-component beam and plate configurations with both structural components of the same material and with thin viscoelastic components (shown cross-hatched). I_n = centroidal moment of inertia of cross-sectional area A_n of component n ; r_n = radius of gyration of A_n ; H_{13} = distance between neutral axes of structural components.

a given composite beam configuration and damping material (at a given frequency and temperature), all parameters that appear in the expression for X then are established, except for the damping material thickness b . Thus, one should choose the value of b that makes X equal to X_{opt} . If this thickness turns out to be impractically small, then one needs to consider an alternative damping material with a greater shear modulus; if the thickness turns out to be too great, one needs to consider use of a damping material with a smaller shear modulus.

5.4 Plates with Viscoelastic Interlayers

A strip of a plate consisting of a viscoelastic layer between two structural layers* may be considered as a special case of three-component beams. All equations and considerations discussed for three-component beams apply here also. Here, however, the expressions for the structural and shear parameters reduce to

$$X = \left(\frac{\lambda}{2\pi} \right)^2 \frac{G_2}{H_2} S \quad \frac{1}{Y} = \frac{E_1 H_1^3 + E_3 H_3^3}{12 H_{13}^2} S$$

$$S = \frac{1}{E_1 H_1} + \frac{1}{E_3 H_3} \quad (12)$$

*A viscoelastic layer between two structural layers is often called a *constrained layer damping treatment*.

5.5 Extensional versus Shear Damping

The damping of beams with single viscoelastic components and of plates with unconstrained viscoelastic layers results primarily due to extension/compression in the viscoelastic material and is independent of the deflection wavelength. On the other hand, the damping of three-component beams and of plates with constrained viscoelastic layers is primarily due to shear in the viscoelastic components and depends markedly on the deflection wavelength. Thus, wavelength considerations need not be taken into account in the design of damping arrangements that depend on extension/compression, but wavelength (and related frequency) considerations are of crucial importance in the design of arrangements that depend on shear. As a result, extensional damping treatments require little design effort and arbitrarily added damping layers are likely to result in some damping benefit. However, shear damping treatments generally need to be designed and arbitrarily assembled arrangements of this type may exhibit very little damping.

Energy dissipation in an extensional damping configuration occurs predominantly at the antinodes of a vibrating structure, whereas energy dissipation in shear damping configurations occurs predominantly at the nodes. Thus, little damping reduction may be expected if viscoelastic material is removed near the nodes of an extensional damping configuration or near the antinodes of a shear damping configuration.

Shear damping treatments clearly are more complex than extensional treatments, but they have some advantages, even though their high-damping performance is limited to their design frequency and temperature range. Shear damping treatments permit one in practice to obtain greater damping in the design range, particularly for heavy structures. Such treatments also generally enable one to achieve a given amount of damping of light structures in the design range with a lesser weight penalty. Finally, because the viscoelastic material in a shear damping configuration can be fully encapsulated, such configurations are useful where interaction of this material with the environment may be a concern.

CHAPTER 61

DYNAMIC VIBRATION ABSORBERS

Leif Kari

The Marcus Wallenberg Laboratory for Sound and Vibration Research
KTH—The Royal Institute of Technology
Stockholm, Sweden

1 INTRODUCTION

Dynamic vibration absorbers (DVA)—also known as antivibrators, vibration neutralizers, and dynamic, tuned, shock, and vibration absorbers or dampers—are auxiliary mechanical systems attached to vibrating systems, whereby the motion of the (primary) vibration systems is reduced. They consist, in their simplest form, of a mass connected to the primary system by a spring and/or a damping element, such as a viscous, hysteric, or friction element. Since their first patent¹ at the beginning of the twentieth century with a prehistory of reducing ship rolling motion at the end of the nineteenth century, they have been extensively used for various engineering applications: To reduce wind-induced vibration in power transmission lines, towers, and skyscrapers, to reduce earthquake-induced bridge and building vibration, and to reduce pedestrian-induced walking bridges vibration. They are, moreover, applied to improve machine tool precision and to reduce helicopter rotor vibration and engine vibration in high-performance automotive racing cars and in light aircraft.

2 SINGLE-DEGREE-OF-FREEDOM SYSTEM

To analyze a single-degree-of-freedom (SDOF) DVA attached to a SDOF primary vibration system appears at a first sight as a rather trivial problem. However, its solution provides general and useful information on vibration absorber efficiency while determining the optimum parameters. In fact, many multi-degrees-of-freedom (MDOF) and continuous systems are condensable into SDOF systems close to their natural frequencies. Moreover, the properties of rotational SDOF DVAs and rotational primary vibration systems are directly attained from their rectilinear analogies by replacing displacement with angle, mass with moment-of-inertia, and force with moment.

2.1 Undamped DVA

Consider the undamped DVA in Fig. 1, consisting of a rigid body of mass m and an idealized spring of stiffness k , attached to a primary vibration system of mass M and stiffness K . A steady-state, harmonic force

$$Q(t) = \text{Re}(Q_0 f^\alpha e^{i\Omega t}), \quad (1)$$

excites the primary system, where t , Ω , and i are time, angular frequency, and the imaginary unit $\sqrt{-1}$, respectively, $f = \Omega/\Omega_0$, and the constant Q_0 is force

magnitude at frequency $\Omega = \Omega_0 (f = 1)$, where the natural frequency of the primary system

$$\Omega_0 = \sqrt{\frac{K}{M}} \quad (2)$$

when considered as a separate SDOF system, and, finally, α is an exponent. This exponent approximates the frequency dependence of the real force and is normally $-2 \leq \alpha \leq 2$, depending on the nature of the force and whether the real forcing system operates in the post- or preresonance mode. The most common values are either $\alpha = 0$ or 2 , where the former represents a flat force spectrum, while the latter a force spectrum proportional to the frequency squared—approximating an inertia reaction to a rotating, unbalanced mass with a frequency-independent eccentricity.

The coupled equations of motion for the primary vibration system and DVA are

$$M \frac{d^2 X}{dt^2} + KX + k(X - x) = Q(t) \quad (3)$$

and

$$m \frac{d^2 x}{dt^2} + k(x - X) = 0 \quad (4)$$

Figure 1 Undamped DVA attached to a primary vibration system.

respectively. The steady-state responses are

$$X(t) = \text{Re}(\hat{X}e^{i\Omega t}) \quad (5)$$

and

$$x(t) = \text{Re}(\hat{x}e^{i\Omega t}) \quad (6)$$

with the normalized solutions

$$\frac{\hat{X}}{X_{st}} = \frac{f^\alpha(f_0^2 - f^2)}{(1 - f^2)(f_0^2 - f^2) - \mu f_0^2 f^2} \quad (7)$$

and

$$\frac{\hat{x}}{X_{st}} = \frac{f^\alpha f_0^2}{(1 - f^2)(f_0^2 - f^2) - \mu f_0^2 f^2} \quad (8)$$

where $X_{st} = Q_0/K$, the relative absorber mass $\mu = m/M$, the tuning $f_0 = \omega_0/\Omega_0$, and the natural frequency of DVA

$$\omega_0 = \sqrt{\frac{k}{m}} \quad (9)$$

when considered as a separate SDOF system.

The normalized displacement $|\hat{X}/X_{st}f^\alpha|$ versus normalized frequency f at $f_0 = 0.75$ and 1.00 is shown in Fig. 2 for a primary vibration system connected to an undamped DVA with a relative mass of $\mu = \frac{1}{10}$. In addition, the result for a primary system without a DVA is shown for comparison. Clearly, the primary vibration system without a DVA has only one resonance at the normalized frequencies $f = 1$, while exhibiting two resonances, when connected to a DVA, at

$$f_{1,2} = \sqrt{\frac{1 + f_0^2(1 + \mu)}{2} \mp \sqrt{\left[\frac{1 + f_0^2(1 + \mu)}{2}\right]^2 - f_0^2}} \quad (10)$$

corresponding to the locations of the poles of Eqs. (7) and (8), and reading $f_{1,2} = 0.71, 1.06$ ($f_0 = 0.75$) and $f_{1,2} = 0.85, 1.17$ ($f_0 = 1.00$) for the studied systems in Fig. 2. Moreover, the system with a DVA has an antiresonance at $f = f_0$, corresponding to the location of the zero of Eqs. (7) and (8). Indeed, the displacement of the primary system vanishes at this frequency while the corresponding DVA displacement is finite, given by Eq. (8) to read

$$\frac{\hat{x}}{X_{st}f^\alpha} \Big|_{f=f_0} = -\frac{1}{\mu f_0^2} \quad (11)$$

Consequently, an undamped DVA attached to a primary vibration system results in the most favorable reduction of the primary system displacement at $f = f_0$. The DVA should therefore be tuned to meet $f_0 = f$. However, this condition is in practice difficult to fulfill. In fact, the excitation frequency Ω may change while the realized DVA parameters may be different from their theoretical values, resulting in $f_0 \neq f$. Those disturbances may result in a poor vibration reduction, as the frequency bandwidth for effective primary system vibration reduction is rather narrow, see Fig. 2. From a physical point of view, the primary system displacement reduction arises from the DVA blocking force, transmitted via the connected spring while the DVA mass moves. No energy dissipation is present as no damping mechanism is involved.

Effect of Mass The bandwidth for possible primary system displacement reduction is determined from the frequency points f_- and f_+ where the relative normalized displacement $|\hat{X}/X_{st}f^\alpha|$ curve, with DVA, in Fig. 2 crosses the corresponding curve, without DVA. These frequency points are

$$f_{-,+} = \sqrt{\frac{2 + f_0^2(2 + \mu)}{4} \mp \sqrt{\left[\frac{2 + f_0^2(2 + \mu)}{4}\right]^2 - f_0^2}} \quad (12)$$

Figure 2 Normalized displacement $|\hat{X}/X_{st}f^\alpha|$ vs. normalized frequency f for a primary vibration system connected to an undamped DVA (solid) and unconnected (dashed). Relative mass $\mu = \frac{1}{10}$.

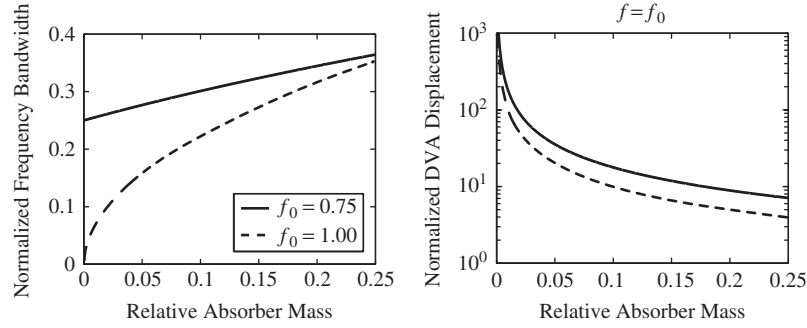

Figure 3 (Left) Normalized frequency bandwidth $f_+ - f_-$ vs. relative mass μ . (Right) Normalized displacement $|\hat{x}/X_{st}f^\alpha|$ vs. relative mass μ at $f = f_0$. Undamped DVA.

The normalized frequency bandwidth $f_+ - f_-$ versus relative mass μ at $f_0 = 0.75$ and 1.00 is shown in Fig. 3 for a primary vibration system connected to an undamped DVA. Also shown is the normalized DVA displacement $|\hat{x}/X_{st}f^\alpha|$ versus relative mass μ at $f = f_0$, using Eq. (11). Note that the DVD displacement is very large at a small relative mass. Clearly, the effective bandwidth increases while the normalized DVA displacement decreases with increased relative mass. However, the main idea of applying a DVA to a real vibrating structure is to use a small relative mass, usually $\mu \leq \frac{1}{10}$, whereas substantially heavier DVA masses—as given by theoretical considerations—call for other vibration reduction procedures, including structural design modifications.

2.2 Viscously Damped DVA

Damped DVAs are applied to allow for energy dissipation, thereby motivating the term *absorber*. These realistic absorbers furthermore reduce their sensitivities to parameter variations from optimal values and reduce the primary system motions at the resonance frequencies f_1 and f_2 , while increasing their effective bandwidth, as compared to their undamped examples. Consider the viscously damped DVA in Fig. 4, being identical to the system in Fig. 1, however, added with a viscous damping element, having a viscous coefficient of c , between the masses.

Consequently, the coupled equations of motion for the primary vibration system and DVA are

$$M \frac{d^2 X}{dt^2} + KX + c \left(\frac{dX}{dt} - \frac{dx}{dt} \right) + k(X - x) = Q(t) \quad (13)$$

and

$$m \frac{d^2 x}{dt^2} + c \left(\frac{dx}{dt} - \frac{dX}{dt} \right) + k(x - X) = 0 \quad (14)$$

respectively, with the normalized solutions

$$\frac{\hat{X}}{X_{st}} = f^\alpha \frac{(f_0^2 - f^2) + i\chi f}{[(1 - f^2)(f_0^2 - f^2) - \mu f_0^2 f^2 + i\chi f(1 - f^2 - \mu f^2)]} \quad (15)$$

Figure 4 Viscously damped DVA attached to a primary vibration system.

and

$$\frac{\hat{x}}{X_{st}} = f^\alpha \frac{f_0^2 + i\chi f}{[(1 - f^2)(f_0^2 - f^2) - \mu f_0^2 f^2 + i\chi f(1 - f^2 - \mu f^2)]} \quad (16)$$

following the same procedure as in Section 2.1, where χ is the damping ratio $\chi = c/\Omega_0 m$.

The normalized displacement $|\hat{x}/X_{st}f^\alpha|$ versus normalized frequency f at $f_0 = 0.75$ and 1.00 is shown in Fig. 5 for a primary vibration system connected to the viscously damped DVA, with a relative mass of $\mu = \frac{1}{10}$ and damping ratios of $\chi = 0, 0.25, 0.50$, and ∞ . Clearly, the finitely damped DVA displays a smoother frequency characteristic than the corresponding undamped ($\chi = 0$) example; thus, avoiding excess displacements at resonances while broadening the effective frequency bandwidth.

Figure 5 Normalized displacement $|\hat{X}/X_{st} f^\alpha|$ vs. normalized frequency f for a primary vibration system connected to a viscously damped DVA. Relative mass $\mu = \frac{1}{10}$ and damping ratios $\chi = 0, 0.25, 0.50$, and ∞ .

The infinitely damped ($\chi = \infty$) example behaves as a SDOF with a mass of $M + m$ standing on the spring of stiffness K , while displaying an undamped resonance at the normalized frequency $f_\infty = 1/\sqrt{1 + \mu}$, reading $f_\infty = 0.95$ for the studied systems in Fig. 5. Not surprising, as the infinitely viscous damper rigidly connects the masses. Moreover, all curves in Fig. 5 pass through two fixed points, regardless of damping, at the invariant frequencies:

$$f_{A,B} = \sqrt{\frac{1 + f_0^2(1 + \mu)}{2 + \mu}} \mp \sqrt{\left[\frac{1 + f_0^2(1 + \mu)}{2 + \mu} \right]^2 - \frac{2f_0^2}{2 + \mu}} \quad (17)$$

reading $f_{A,B} = 0.73, 1.01$ ($f_0 = 0.75$) and $f_{A,B} = 0.88, 1.10$ ($f_0 = 1.00$) for the studied systems.

The optimal parameter values are determined by a procedure originally developed by Den Hartog² while using the properties of the fixed points at the frequencies given by Eq. (17). This fixed-point method is considered highly accurate as a design method for viscously damped DVA.³ The main idea is to derive the optimal tuning f_0^{opt} from the requirement of equal displacement magnitudes at the fixed points $|\hat{X}(f_A)| = |\hat{X}(f_B)|$, while the optimal damping ratio χ^{opt} is determined from the requirement of vanishing slopes at the fixed points $d|\hat{X}(f_A, \chi_A^{\text{opt}})|/df = 0$ and $d|\hat{X}(f_B, \chi_B^{\text{opt}})|/df = 0$, where the optimal damping ratio governs from its mean squares $\chi^{\text{opt}} = \sqrt{[(\chi_A^{\text{opt}})^2 + (\chi_B^{\text{opt}})^2]/2}$. The optimal parameter values are shown in Table 1 in terms of the relative mass μ and excitation force exponent α .

The normalized displacement $|\hat{X}/X_{st}|$ versus normalized frequency f , for a force excitation exponent of $\alpha = 0$ and 2, is shown in Fig. 6 for a primary vibration system connected to an optimally damped viscous DVA with a relative mass of $\mu = \frac{1}{10}$. The optimal parameters read $f_0^{\text{opt}} = 0.91$, $\chi^{\text{opt}} = 0.34$ ($\alpha =$

Table 1 Optimal Parameter Values for a Damped DVA

α	$f_{A,B}$	f_0^{opt}	χ^{opt}	η^{opt}
0	$\sqrt{\frac{1 \mp \sqrt{\frac{\mu}{2 + \mu}}}{1 + \mu}}$	$\frac{1}{1 + \mu}$	$\sqrt{\frac{3\mu}{2(1 + \mu)^3}}$	$\sqrt{\frac{\mu(3 + 2\mu)}{2 + \mu}}$
2	$\sqrt{\frac{1 \mp \sqrt{\frac{\mu}{2(1 + \mu)}}}{1 + \frac{\mu}{2}}}$	$\sqrt{\frac{1}{1 + \mu}}$	$\sqrt{\frac{3\mu}{(2 + \mu)(1 + \mu)}}$	$\frac{\sqrt{3\mu(2 + 3\mu)}}{2 + \mu}$

Source: From Ref. 4.

0) and $f_0^{\text{opt}} = 0.95$, $\chi^{\text{opt}} = 0.36$ ($\alpha = 2$). In addition, the results for a primary system with an undamped DVA and without a DVA are shown for comparison. Clearly, the optimally damped DVA displays a flat frequency characteristic while avoiding the displacement peaks at the resonance for the corresponding undamped example. The effective frequency bandwidth is therefore increased.

2.3 Hysteretic Damped DVA

The energy dissipation in many engineering damping materials, such as rubber and plastics, are preferably expressed by a hysteretic damping model with a spring stiffness of $k(1 + i\eta)$, where η is a loss factor, normally considered as frequency independent. Consider the hysteretic damped DVA in Fig. 7, being identical to the system in Fig. 1, but with a complex valued stiffness.

Accordingly, the coupled equations of motion for the primary vibration system and DVA are

$$M \frac{d^2 X}{dt^2} + KX + k(1 + i\eta)(X - x) = Q(t) \quad (18)$$

and

$$m \frac{d^2 x}{dt^2} + k(1 + i\eta)(x - X) = 0 \quad (19)$$

Figure 6 Normalized displacement $|\hat{X}/X_{st}|$ vs. normalized frequency f for a primary vibration system connected to an optimally damped viscous DVA. Relative mass $\mu = \frac{1}{10}$, optimal tuning and optimal damping ratio.

Figure 7 Hysteretic damped DVA attached to a primary vibration system.

respectively, with the normalized solutions

$$\frac{\hat{X}}{X_{st}} = f^\alpha \frac{(f_0^2 - f^2) + i\eta f_0^2}{[(1 - f^2)(f_0^2 - f^2) - \mu f_0^2 f^2 + i\eta f_0^2(1 - f^2 - \mu f^2)]} \quad (20)$$

and

$$\frac{\hat{x}}{X_{st}} = f^\alpha \frac{f_0^2 + i\eta f_0^2}{[(1 - f^2)(f_0^2 - f^2) - \mu f_0^2 f^2 + i\eta f_0^2(1 - f^2 - \mu f^2)]} \quad (21)$$

following the same procedure as in Sections 2.1 and 2.2.

The procedure of optimizing the parameters to a hysterically damped DVA is almost identical to that of a viscous damped DVA in Section 2.2, with

optimal parameter values shown in Table 1.⁴ The normalized displacement $|\hat{X}/X_{st}|$ versus normalized frequency f , for a force excitation exponent of $\alpha = 0$ and 2, is shown in Fig. 8 for a primary vibration system connected to an optimally damped hysteretic DVA with a relative mass of $\mu = \frac{1}{30}$. The optimal parameters read $f_0^{\text{opt}} = 0.97$, $\eta^{\text{opt}} = 0.22$ ($\alpha = 0$) and $f_0^{\text{opt}} = 0.98$, $\eta^{\text{opt}} = 0.23$ ($\alpha = 2$). The results for a primary system with an undamped DVA, and without a DVA are shown for comparison. Obviously, the results are similar to that of a viscous damped DVA, displaying a smooth frequency characteristic over a broad frequency range, including the two undamped resonances.

2.4 Damped DVA and Primary Vibration System

Consider the systems in Fig. 9, consisting of damped DVAs attached to damped primary vibration systems, displaying a damping mechanism of either viscous or hysteretic type. The determination of the primary system and DVA responses is straightforward, following the examples in Sections 2.1 to 2.3, resulting in slightly more involved expressions.⁴⁻⁷ However, the Den Hartog method of fixed points for parameter optimization is not exactly applicable, as those points are missing for these systems, thus, calling for approximate or numerical methods. Fortunately, the optimal parameter values are close to those in Sections 2.3 and 2.4 for lightly damped primary systems (compared to the damping of DVAs). Moreover, DVAs are primary intended for undamped and lightly damped systems, whereas substantially more damped primary systems generally require other vibration suppression measures.

3 MULTI-DEGREES-OF-FREEDOM SYSTEM

The SDOF DVAs and primary vibration systems treated hitherto are readily extended into MDOF arrangements, either by allowing for a MDOF DVA, shown in Fig. 10, or for a MDOF primary vibration systems or for both being of MDOF, the former shown

Figure 8 Normalized displacement $|\dot{X}/X_{st}|$ vs. normalized frequency f for a primary vibration system connected to an optimally damped hysteretic DVA. Relative mass $\mu = \frac{1}{30}$, optimal tuning and optimal loss factor.

Figure 9 Damped DVA and primary vibration system. Viscous (left) and hysteretic (right).

to the left in Fig. 11, while the latter to the right. Multi-mass/spring DVAs are applied for a number of various reasons: to distribute their action on the primary vibration system, to reduce the individual damper mass and size, and to enlarge their effective bandwidth (as compared to the mono-mass/spring DVA), to mention just a few examples.⁴ However, attention to ensure that the added mass displacements are not excessively large is needed.

The design scheme for simple mass–spring DVAs, developed in Section 2, is successfully applied for MDOF primary vibration systems with well-separated natural frequencies, such as beams.^{4–7} This procedure is not suggested for primary systems with a dense spectrum of natural frequencies, such as hipped plates and shells.

A fruitful method to reduce the vibrations of an MDOF primary vibration system is to use a single MDOF DVA, which is simultaneously effective at several resonance frequencies, such as a plate or beam DVA of infinitely many DOF, shown to the right in Fig. 11.

4 DESIGN CONSIDERATIONS

Unlike other vibration reduction procedures, DVAs are possible to specify and design not only at the drawing and construction stage of the primary vibrating system but also during its operational phase, in this manner suppressing unwanted and maybe unexpected vibrations. Moreover, the application of DVAs is considered as a fairly economical method to reduce vibrations.

There is a great variety of DVA and primary system designs. The undamped mass–spring DVA is the simplest configuration. However, this narrow-band tuned DVA is in practical application of little use as the excitations frequency generally varies and the realized damping and stiffness commonly differ from their optimal values. In practice, damped DVAs are used to enlarge the effective frequency range, while introducing an energy dissipation mechanism. Occasionally, detachable DVA masses of various weights are employed for fine tuning. Multi-mass/spring DVAs are also applicable.

Steel and rubber springs are often employed in DVAs. Hydraulic, pneumatic, and magnetic dampers,

Figure 10 MDOF DVA attached to a SDOF primary vibration system. Parallel (*left*) and series (*right*) connection.

Figure 11 SDOF DVA (mass-spring-damper) (*left*) and MDOF DVA (cantilever beam-spring) (*right*) attached to a MDOF primary vibration system (clamped beam or plate).

wired steel ropes, and polymer elements, such as from rubber and plastic, are frequently applied as the energy dissipation component of the DVA. The employed damping models are of a viscous, hysterical, and, in some cases, of a Coulomb friction type. From the designer's point of view, the optimal loss factor required in Table 1 for a typical relative mass exceeds the realistic loss factor for many engineering materials showing hysteretic damping, including natural rubber. As a result, the relative mass must be decreased, in this way limiting the required loss factor to a realistic level. However, the maximum displacement of the DVA is then increased.

The design procedure outlined in this chapter is also applicable for multiharmonic excitation of the primary vibrating system. A damped DVA is then used for each excitation frequency. Continuous DVA structures, such as beams and plates, are also applicable while being simultaneously effective at several frequencies.

5 EXCURSION

Although harmonic forces are the most common primary vibration system excitation, other signals may exist, such as transients, random, and periodic

impulses. Their solutions are somewhat different from those given in this chapter.⁴ Likewise, there are other types of DVAs: pendulum, nonlinear, liquid, and granular-material-filled DVAs, to mention just a few examples. The interested reader is referred to textbooks on DVAs.⁴⁻⁸

Recently, active DVAs are applied, generally providing more effective vibration suppression than their inactive counterparts, however, to the cost of higher complexity and larger outlays. Smart materials are also applied to DVAs, including piezoelectric, electro-, and magnetorheological materials. A survey on recent progress of passive, adaptive, and active DVAs is presented by Sun et al.⁹

CHAPTER 62

ROTOR BALANCING AND UNBALANCE-CAUSED VIBRATION

Maurice L. Adams, Jr.

Department of Mechanical and Aerospace Engineering
The Case School of Engineering
Case Western Reserve University
Cleveland, Ohio

1 INTRODUCTION

A rotor is said to be unbalanced if its *mass axis* does not coincide with its axis of rotation. A *mass axis* is the locus of the distributed *mass-center* along the rotor length. Rotor balancing is the most important and frequently addressed day-to-day operation in achieving smooth running rotating machinery. It starts with the basic machine design process coupled with the construction details of the rotor, including shop rotor balancing of new and repaired rotors using a *balancing machine*. For some machinery types and applications, this is all that may ever be required. However, in-service rebalancing of some machinery types is periodically needed to reduce their residual unbalance-driven vibration to within acceptable levels, being guided by an experienced-based criterion. There is a sharp distinction between *shop balancing* a rotor in a balancing machine and *in-service field balancing* a rotor in an assembled machine. When shop balancing a new or just repaired rotor, the bare exposed rotor is mounted in a balancing machine and balance correction weights may be placed at any of the balance correction axial planes designed into the rotor. Conversely, in-service rotor balancing usually dictates that balance correction weights can be added only at balance correction planes that are readily accessible while the rotor is installed in an operational machine.

2 NEED FOR ROTOR BALANCING

The mass axis does not exactly coincide with the axis of rotation of a rotor because of manufacturing inaccuracies and accumulated in-service balance degradation effects. The mass axis is the locus of the distributed mass center along the rotor length as illustrated in Fig. 1. Rotor balancing to achieve smooth operation of rotating machinery is necessary in most cases. It starts with the basic machine design process coupled with the construction details of the rotor, including shop rotor balancing of new and repaired rotors using a balancing machine. Figure 2 typifies two in-service machine vibration records where rebalancing will be necessary. Figure 3 shows a typical experienced-based guideline for vibration level assessment to determine if rebalancing is needed.

That the subject of rotor balancing warrants its own book was rectified by Rieger,¹ which is the most

Figure 1 Isometric view of a general rotor unbalance axial distribution.

complete and comprehensive treatise on the subject to date. In addition to fundamental theory and application details for different balancing methods and balancing machines, Ref. 1 also provides a historical perspective on rotor balancing and a summary of balancing specifications for the different classes of machines. Thus, it provides coverage of the field both as needed by the designer/builder of rotating machinery as well as the in-service user/maintainer of rotating machinery. If one is just beginning to study rotor balancing, it is helpful to delineate between so-called *static unbalance* and *dynamic unbalance* as well as distinguish between so-called *rigid rotors* and *flexible rotors*. Due to some ever-present residual rotor mass unbalance, the largest vibration component is usually at the rotating-speed frequency. Figure 3 is a typical example guideline for assessment of operating machines, not a purchase specification acceptance standard.

3 STATIC UNBALANCE – SINGLE-PLANE BALANCE CORRECTIONS

The simplest rotor unbalance condition is characterized by the rotor mass center being eccentric to the rotor's geometric spin axis. This is called *static unbalance*. A static unbalance can be likened to an unbalance mass (m_s) at some nonzero radius (r_s) superimposed (in the radial plane of the rotor's mass center) upon an otherwise perfectly balanced rotor, as illustrated in Fig. 4. Such a concentrated static unbalance clearly acts on the rotor like an equivalent synchronous co-rotational force ($F_u = m_s r_s \omega^2$) that is fixed in the rotor

Figure 2 Trending unbalance vibration over time.

Figure 3 Bearing cap operating vibration displacement guideline. Allowable: operating zone only for short periods.

Figure 4 Combination of static and dynamic rotor disk unbalance.

(Fig. 5). Thus, a purely static unbalance on a simple rotor configuration as in Fig. 4 can theoretically be corrected by a single balance correction weight with the same magnitude ($m_s r_s$) and in the same radial plane as the initial static unbalance, but positioned 180° from the initial unbalance.

Figure 5 Model representation of an unbalance force upon the rotor.

That is, static unbalance is theoretically correctable by adding a balance correction mass in a *single plane*, specifically, in the plane of the unbalance. A quite common example of single-plane balancing is automotive tire-wheel units that are relatively narrow axially compared to their diameter and are thus approximated as a single-plane mass distribution rotor. The reason for spinning the tire-wheel unit in the tire shop balancing machine is to produce a sufficiently large measurement of the static unbalance force, not to perform a true dynamic balance (see next section). Furthermore, the reason the competent tire shop mechanic places half the weight correction on the outside rim and half on the inside rim (both at same angle) is so that the added static-balance correction weights do not produce a dynamic unbalance. There are many other examples where single-plane balancing produces an adequate state of rotor balance quality.

The two equations of motion for this model with the shown rotating excitation force are easily derived from $F = ma$ to obtain the following:

$$m\ddot{x} + c_x\dot{x} + k_x x = F_0 \cos \omega t$$

$$m\ddot{y} + c_y\dot{y} + k_y y = F_0 \sin \omega t$$

4 DYNAMIC UNBALANCE – RIGID-ROTOR TWO-PLANE BALANCE CORRECTION

Dynamic unbalance refers to rotor unbalance that acts like an equivalent radial co-rotational moment fixed

in the rotor. Referring again to Fig. 4 and using its nomenclature, the equivalent co-rotational moment of a concentrated dynamic unbalance has magnitude $M_d = m_d r_d l \omega^2$. If rotor flexibility is not a significant factor to unbalance vibration response, then the *rigid-rotor* assumption can be invoked. Then the total dynamic unbalance of a rotor is theoretically correctable by adding two equal-magnitude ($m_c r_c$) corrections (separated by 180°), one at each of two planes axially separated by l_c (where $m_c r_c l_c = m_d r_d l$). The two $m_c r_c$ corrections are positioned in the plane of the initial dynamic unbalance, but 180° out of phase with the initial dynamic unbalance. The initial dynamic unbalance is thereby theoretically negated since the co-rotational moment produced by the two correction masses has the magnitude $m_d r_d l \omega^2$ of the initial dynamic unbalance, but 180° out of angular position with the co-rotational moment produced by the initial dynamic unbalance. Since a static unbalance can be negated by two in-phase correction weights appropriately placed in the same two planes as the dynamic unbalance correction masses, it is clear that a complete rotor balance (static + dynamic) of a "rigid" rotor can be accomplished by adding correction masses in only two planes. Since a general state of rotor unbalance is a combination of both static and dynamic unbalance, the correction weights at different axial locations will generally be neither at the same angular position but separated exactly by a 180° in their relative angular positions.

The defining property for so-called rigid rotors is that rotor flexibility is not a significant factor to unbalance vibration response. Therefore, the *two-plane* balance procedure for a rigid rotor can be performed at a speed lower than the operating speed of the rotor. In practical terms, this means the rotor may be balanced using vibration or dynamic force measurements at balancing spin speeds substantially lower than the rotor's in-service operating speed.

5 UNBALANCED FLEXIBLE ROTORS — MULTIPLANE BALANCE CORRECTIONS

A *flexible rotor* can be defined as being any rotor that cannot be effectively balanced throughout its speed range by placing suitable correction weights in two separate planes along its length. Synonymous with this definition is that a so-called flexible rotor has an operating speed range that closely approaches or encompasses one or more bending critical speeds whose rotor flexural bending contributes significantly to the corresponding critical speed mode shape(s) and unbalance vibration responses. Table 1 provides an introductory composite description of the increased rotor dynamic complexity produced when rotor flexibility is significant to unbalance vibration characteristics.

In contrast to a rigid rotor, adequate balancing of a flexible rotor often requires placement of correction weights in more than two separate planes along the rotor length. The adequate number of balancing planes and their optimum locations along the rotor are dictated by the mode shape(s) of the critical speed(s) that

significantly affect the rotor's unbalance vibration response. The first three flexure mode shapes of a uniform simply supported beam are illustrated in Fig. 6 and provide some insight into proper axial locations for balance correction weights in balancing flexible rotors. That is, for a rotor with critical speed mode shapes similar to those in Fig. 6, a mid-span balance plane clearly has maximum effectiveness on the first mode. Similarly, the $\frac{1}{4}$ and $\frac{3}{4}$ span locations have maximum effectiveness on the second mode, and the $\frac{1}{6}$, $\frac{1}{2}$, and $\frac{5}{6}$ span locations have maximum effectiveness on the third mode.

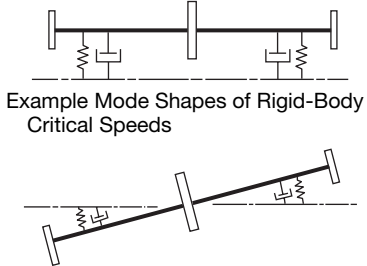

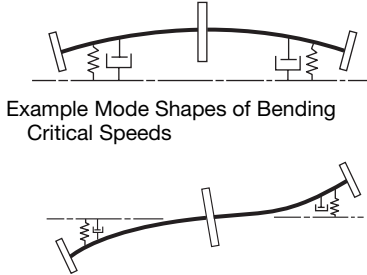

A flexible rotor is also definable as one with a dynamic bending shape that changes with rotational speed, and this speed-dependent dynamic bending may alter the state of balance. Ideally, a flexible rotor should therefore be balanced at full in-service rotational speed and at speeds near critical speeds within or near the operating speed range. This point is clearly demonstrated by an example from Ref. 2 illustrated in Fig. 7, which shows a uniform shaft in stiff bearings unbalanced by a single mass attached at the axial center of the shaft. Figure 7 also illustrates that the shaft has been rebalanced consistent with the low-speed rigid-rotor approach by adding a correction weight at each end of the shaft. As long as the shaft speed is significantly below its first bending critical speed, it will remain essentially straight and thus will remain in balance. But as its rotational speed approaches its first bending critical speed, it vibrates as illustrated in Fig. 8 (illustrated vibration deflection grossly exaggerated).

As is clear from Fig. 8, at speeds near its first bending critical speed the shaft illustrated in Fig. 7 has its initial unbalance and both unbalance correction weights acting in collaboration to excite the first bending critical speed. If this experiment were performed, one would find that the vibration near the first bending critical speed would be worse (higher) with the two low-speed-balancing correction weights attached than without. In this simple example, the initial unbalance is known to be concentrated at the mid-span location and thus it is a trivial case. In a general case with manufacturing and assembly tolerances, the unbalance is of an unknown distribution along the rotor, such as that illustrated in Fig. 1.

Balancing a dynamically flexible rotor is a considerably more involved process than low-speed two-plane balancing of rigid rotors. Each type of flexible rotor has its own preferred number and location of balance planes. Many multistage machines require a component balance of each impeller or bladed disk assembly before mounting and only then balancing the fully assembled rotor, for example, aircraft gas turbine jet engines.

Some flexible rotors can be adequately well balanced like a rigid rotor, that is, on a low-speed balancing machine with correction masses placed in only two planes along the rotor length. Such a rotor is characterized by having most of its unbalance concentrated at a known axial region of the rotor, for example, large double suction power plant centrifugal fans. There are

Table 1 Three Elementary Rotor Lateral Vibration Complexity Categories

#	System Category	Design Considerations
1	Maximum speed below 80% of lowest critical speed 	Two-plane low-speed rigid-body balancing is all that is required. No elaborate analyses required.
2	Maximum speed is near lowest critical speed or above 1 or 2 critical speeds, but bearings are sufficiently soft that critical-speed modes are rigid-body like. 	Must calculate critical speed(s) to avoid continuous operation at or near a critical speed. Recommend analysis prediction of vibration amplitudes at critical speeds versus amount of available damping. Should also check for self-excited instability rotor vibration. Two-plane low-speed rigid-body balancing is adequate because rotor dynamic flexibility is not significant.
3	Maximum speed near or above one or more critical speeds and rotor flexing is a significant part of critical-speed mode shapes. 	Same recommendations as category 2, except that it will likely be necessary to perform multiplane rotor balancing at speeds up to the maximum operational speed because of the importance of bending critical speeds

Note: Rotor dynamic complexity increases with number.

**Figure 6** First three planar mode shapes for a simply supported uniform beam.

a number of competing methods for balancing flexible rotors, the two most recognized being the *modal method* and the *influence coefficient method* (ICM).

**Figure 7** Simple uniform diameter flexible rotor.

Both of these assume that the rotor dynamic system is linear. Significant nonlinearity can be tolerated, but it will likely increase the number of balancing iterations needed to achieve the required quality of rotor balance. The *modal method* requires detailed modal information (mode shapes) for all the critical speeds that significantly influence the rotor's unbalance vibration characteristics over its entire speed range. To the

Figure 8 Vibration mode shape of a first bending critical speed.

extent that critical-speed modal characteristics are a function of radial bearing dynamic characteristics, the bearings in a modal balancing machine need to match the dynamic characteristics of the actual machine's bearings, and this is often not practical. Thus, although the modal method is considered in some circles to be theoretically a more effective approach than the ICM for balancing flexible rotors, in practice the ICM is used in most applications, being less complicated and more practical than the modal method. The strong preference for the ICM is particularly true for in-service rebalancing of rotors in assembled machines, where a correction is often limited to one plane.

6 INFLUENCE COEFFICIENT METHOD

The ICM does not require critical-speed mode shapes, but approximate mode shapes can be helpful in the design process to prescribe where balance planes and unbalance vibration measurements are best located. However, after a rotor is installed in its machine, accessible planes for rebalancing are often limited to locations near the axial ends of the rotor, for example, at a coupling. Thus, all the potential benefits of multiplane rotor balancing are only of academic interest to the person in the power plant who must implement a "balance shot" during a short outage of a machine. A general summary of the ICM fashioned after Ref. 2 is presented here. Free software (disk) for general-purpose ICM balancing is available in Ref. 3 and includes several balancing examples using that software. Utilizing the basic dynamic linearity assumption, the rotor vibration response can be given as the superposition or sum of individual vibration responses from an unbalance at each of the selected balance planes, as expressed in the following equation:

$$V_j = \sum_{k=1}^{N_p} A_{jk} U_k \quad j = 1, 2, \dots, N_m$$

$$k = 1, 2, \dots, N_p \quad (1)$$

where N_m = number of independent vibration observations = number of locations \times number of speeds

N_p = number of balance planes

V_j = vibration response from j th measurement $\equiv \mathbf{V}_j e^{i(\omega t - \theta_j)}$ (complex)

U_k = unbalance at k th balance correction plane $\equiv \mathbf{U}_k e^{i(\omega t + \phi_k)}$ (complex)

A_{jk} = influence coefficient $N_m \times N_p$ array $\equiv \mathbf{A}_{jk} e^{i\alpha_{jk}}$ (complex)

Since the ICM is based only on the assumption of linear dynamic characteristics, nonplanar modes are automatically accommodated.

Vibration measurements need not be taken at the same locations as the balance correction planes. Also, any and all of the three commonly used vibration sensor types may be used, that is, accelerometer, velocity pickup, and proximity probe (displacement). Furthermore, vibration measurements may be made on adequately responsive nonrotating parts of the machine (e.g., bearing caps). For in-service rebalancing of machines with displacement probes installed (typically mounted on the bearings targeting the shaft), the rotor vibration relative to the bearing(s) may be used provided the shaft target mechanical and electrical runout are known and correctly subtracted from the total probe signals.³

The influence coefficients are experimentally obtained by measuring the incremental change in each of the measured vibration responses to a *trial mass* individually placed at each balance correction plane. With the influence coefficients known, balance corrections for each correction plane can be computed. After the correction masses ($W_j, j = 1, 2, \dots, N_p$) are installed, the residual rotor vibration for all the specified observations (locations and speeds) are expressible as follows, where $V_j^{(0)}$ are the measured vibration responses before adding the balance correction masses:

$$V_j = V_j^{(0)} + A_{jk} W_k \quad (2)$$

If the number of observations ($N_m \geq N_p$) is equal to the number of balance correction planes ($N_m = N_p$), then the influence coefficient array A_{jk} yields a square matrix that is presumably nonsingular by virtue of making N_m linearly independent vibration measurement observations. Using Eq. (2), unbalance vibration at the observation locations and speeds can then theoretically be made zero by using balance corrections given by the following equation:

$$\{W\} = -[A]^{-1}\{V^{(0)}\} \quad (3)$$

It is widely suggested that better balancing often results if the number of observations exceeds the number of correction planes, that is, $N_m > N_p$. Since it is then mathematically impossible to make all the observed vibrations go to zero, the approach generally taken is to base the balance correction masses on minimizing the sum of the squares of the residual observed vibrations.

What the ICM can theoretically achieve is best understood by considering the following. If the system were perfectly linear and the vibration observation measurements were made with zero error, then for the case of $N_m = N_p$, the observed vibrations (at location-speed combinations) are all made zero by the correction masses. Similarly, for the case of $N_m > N_p$, the sum of the squares of the residual observed vibrations can be minimized. However, there

is no mathematical statement for unbalance vibration amplitudes at any other location–speed combinations. By choosing balance speeds near all important critical speeds and at maximum operating speed, and balance planes where actual unbalance is greatest, as well as choosing vibration measurement points that are not close to critical speed mode-shape nodal points, smooth running over the full speed range is routinely achievable.

7 IN-SERVICE SINGLE-PLANE BALANCE “SHOT”

The most common day-to-day type of rotor balancing is the in-service balance shot, especially in power plants, process plants, and machine tool spindles. In these rotor balancing efforts, the machine is in-service and unbalance-caused vibration had increased (perhaps gradually) above allowable maximum amplitude levels (see Figs. 2 and 3). Typically, a balance correction weight is placed at a single plane which is readily accessible on a fully assembled machine. In power plants and process plants it is essential that the balancing shot can be accomplished as quickly as possible so the machine can be returned to operation (e.g., during a short weekend machine outage).

The objective of such single-plane in-service balance shots is to reduce the steady-state machine maximum vibration amplitudes. That is, it is not intended, nor is it feasible, that such single-plane balance shot provide the high degree of rotor balance quality that is achievable when the removed bare rotor is factory balanced in a precision balancing machine.

A caveat is appropriate to mention at this point. Reference 3 shows that a balance shot placed at a readily accessible rotor location may reduce the measured vibration levels, but may not appreciably reduce rotor vibration levels at machine internal locations where vibration measurements cannot be obtained and where balance weights cannot be placed. Thus, the small internal radial clearances between rotating and nonrotating components at mid-span locations (e.g., at turbine and compressor blade tips and pump sealing wear rings) may not benefit from such a balance shot, as Fig. 8 clearly demonstrates.

Applying the ICM to a single-plane balance shot can be illustrated on a polar phasor vector plot of the steady-state once-per-revolution (synchronous) vibration. Plant rotor balancing personnel often use such a polar plot to graph the amount and angular location of the balance correction weight. This is illustrated in Fig. 9 and is appropriate for any system of units and vibration measure (i.e., displacement, velocity, or acceleration). All boldface letters denote complex-valued phasor vectors. It is assumed that the trial weight (U_T , used to balance calibrate the system) is first removed before attaching the correct weight (U_c) that theoretically brings the measured vibration to zero:

$$x = X \cos(\omega t + \theta) \quad \text{measured synchronous vibration signal}$$

ω = rotor angular velocity (rad/s) CCW,

θ = phase angle

$e^{i\theta} = \cos \theta + i \sin \theta$, $\text{Re} \rightarrow$ real axis,

$\text{Im} \rightarrow$ imaginary axis, $i = \sqrt{-1}$

8 CONTINUOUS AUTOMATIC IN-SERVICE ROTOR BALANCING

No comprehensive discussion on rotor balancing would be complete without mentioning automated real-time continuous rotor balancing systems. Figure 10 shows a cut-away view of an automatic balancing system. The rotor-mounted portion houses two equally unbalanced counterweight/stepping-motor rotors, separately indexed in 5° (or less) increments relative to the rotor. Power and control are through magnetic couplers.

Conventional rotor-mounted automatic balancing devices are designed to minimize residual rotor mass unbalance so that the rotor vibration level is maintained within a given application's requirements. Precision machine tool spindles, especially for grinding, are a major application for such devices since successful high-volume high-precision grinding requires continual automatic adjustment of balance correction weights on the rotating assembly as grinding wheel material is removed. The conventional devices available for such automated balancing are configured to change the correction weight magnitude and angular location based on many successive incremental moves that reduce the monitored vibration (usually measured with an accelerometer attached to the spindle housing). However, such conventional systems do not “know” the magnitude or angular location of the continuously changed correction weight nor are they able to execute a “command” to perform a specified incremental change to the correction weight.

Automatic balancing systems, such as shown in Fig. 10, have significantly advanced the field of automatic rotor balancing by tracking the magnitude and angular location of the instantaneous balance correction. The author has recently designed and constructed a new flexible-rotor test rig (Fig. 11) that is configured with two of such automatic rotor balancing devices. The software supplied with these two matched devices executes real-time two-plane automatic rotor balancing, with the controlling algorithm based on the influence coefficient method. The software also permits manual control of counterweight placement and magnitude [through a host PC (personal computer) controller]. That feature plays prominently in current ongoing model-based monitoring and diagnostics research in the author's laboratory.⁴ That is, by being able to impose a known incremental change to the state of unbalance (i.e., active probing of the dynamical system), a continuous real-time comparison can be made between how the actual machine incrementally responds and how an observer model tracking the machine's vibration responds.

"Key phasor" is a fixed point on the shaft

U_T and ΔX are locked together in phase angle and magnitude proportion

$$\Delta X = C U_T \therefore C = \frac{\Delta X}{U_T} = \frac{\Delta X e^{i\theta_{\Delta X}}}{U_T e^{i\theta_{U_T}}} = \frac{\Delta X}{U_T} e^{i(\theta_{\Delta X} - \theta_{U_T})}, \theta_{U_T} - \theta_{\Delta X} = \text{constant}$$

$$\text{Zero vibration condition} \quad X_1 + C U_c = 0 \therefore U_c = -\frac{X_1}{C} = \frac{-X_1 e^{i\theta_1}}{C e^{i(\theta_{\Delta X} - \theta_{U_T})}} = \frac{-X_1}{C} e^{i(\theta_1 - \theta_{\Delta X} + \theta_{U_T})}$$

Figure 9 Polar phasor vector plot of a single-plane balance correction.

Figure 10 Automatic rotor mass balancer. (Courtesy of Lord Corporation.)

The author believes this new type of real-time automatic balancing system can be a quite cost-effective method for minimizing rotor vibration levels on flexible-rotor machines that currently necessitate considerable compromises between various important critical speeds and operating speeds that each are somewhat unique as to optimum balance correction weight placements. Many

large steam turbo-generator configurations now in service would benefit considerably from such a system, reducing the time required for rebalancing after a major scheduled outage by allowing the balance corrections to be made "on the fly" as the unit is slowly rolled up to synchronous operating speed, and likewise when the unit is taken off line as it coasts down to turning gear speed.

CHAPTER 63

ACTIVE NOISE CONTROL

Stephen J. Elliott
Institute of Sound and Vibration Research
University of Southampton
Southampton, United Kingdom

1 INTRODUCTION

Active noise control is a method of reducing sound by destructive interference between the fields of the original, *primary*, source and a number of controllable, *secondary*, sources. The number of secondary sources required depends on the complexity of the sound field. For plane waves propagating in a duct, a single secondary source can be used to reflect the primary wave, or two sources can be used to absorb it. In free space, the number of secondary sources required to control a compact primary source increases as the square of the distance of the secondary source away from the primary source. In an enclosure the number of secondary sources required for control of the sound field depends upon the acoustical modal overlap and at higher frequencies increases as the cube of the frequency. Current industrial applications include the control of sound in ventilation and exhaust ducts, the control of sound in propeller aircraft, and active headsets.

2 CONTROL OF WAVE TRANSMISSION

In this section, we consider the active control of sound that is transmitted as plane propagating waves in a uniform duct.^{1,2} For sufficiently low frequency excitation only *plane waves* of sound can propagate in such a duct. In that case the waves have a uniform pressure distribution across any section of the duct and obey the one-dimensional wave equation. The fundamental approaches to active wave control can be illustrated using this simple example, but some of the complications involved in controlling higher order modes in ducts are also briefly discussed at the end of the section.

2.1 Sound Cancellation

To begin with, it will be assumed that an incident harmonic sound wave, traveling in the positive- x direction along a duct, is controlled by a single acoustic secondary source such as a loudspeaker mounted in the wall of the duct, as illustrated in Fig. 1a. The duct is assumed to be infinite in length, to have rigid walls, and to have a uniform cross section. The complex pressure of the incident primary wave is expressed as

$$p_{p+}(x) = Ae^{-jkx} \quad \text{for all } x \quad (1)$$

where the subscript $p+$ denotes the primary wave traveling in a positive- x direction, or *downstream*. An acoustic source, such as a loudspeaker driven at the same frequency as that of the incident wave, will produce acoustic waves traveling both in the

Figure 1 (a) Active control of plane sound waves in an infinite duct using a single secondary source. (b) Amplitude of the pressure distribution in an infinite duct after a single secondary source, at $x = 0$, has been adjusted to cancel an incident plane wave of unit amplitude travelling in the positive x direction.

downstream direction and in the *upstream* or negative- x direction, whose complex pressures can be written as

$$p_{s+}(x) = Be^{-jkx} \quad \text{for } x > 0, \quad (2a)$$

$$p_{s-}(x) = Be^{+jkx} \quad \text{for } x < 0 \quad (2b)$$

where the secondary source has been assumed to be at the position corresponding to $x = 0$, and B is a complex amplitude that is linearly dependent on the electrical input to the secondary source u in Fig. 1a. If this electrical input is adjusted in amplitude and phase so that $B = -A$, the total downstream pressure will be

$$p_{p+}(x) + p_{s+}(x) = 0, \quad \text{for } x > 0 \quad (3)$$

indicating that the pressure will be perfectly canceled at all points downstream of the secondary source. This

suggests that a practical way in which the control input could be adapted is by monitoring the tonal pressure at any point downstream of the secondary source and adjusting the amplitude and phase of the control input until this pressure is zero. The practicalities of such adaptive feedforward controllers are described by Elliott.² However, we are mainly interested here in the physical consequences of such a control strategy, and so we calculate the total pressure to the left, on the upstream side of the secondary source, which in general will be

$$p_{p+}(x) + p_{s-}(x) = Ae^{-jkx} + Be^{+jkx} \quad x < 0 \quad (4)$$

If the secondary source is adjusted to cancel the pressure on the downstream side, then $B = -A$, and the pressure on the upstream side becomes

$$p_{p+}(x) + p_{s-}(x) = -2jA \sin kx \quad x < 0 \quad (5)$$

since $e^{jkl} - e^{-jkl} = 2j \sin kl$. Thus a perfect acoustic *standing wave* is generated by interference between the positive-going primary wave and the negative-going wave generated by the secondary source. Notice that this standing wave has nodes of pressure at the position of the secondary source, $x = 0$, and at $x = -\lambda/2$, $x = -\lambda$, and so on, where λ is the acoustic wavelength, and that when $x = -\lambda/4$, $x = -3\lambda/4$, and so on, its amplitude is exactly twice the amplitude of the incident primary wave. The distribution of the pressure amplitude in the duct under these circumstances is shown in Fig. 1b.

In canceling the pressure downstream of the secondary source, the pressure at the secondary source location has been driven to zero by the effect of the active control system. The secondary source thus acts to create a pressure-release boundary condition as far as the incident wave is concerned and effectively *reflects* this wave back up the duct with equal amplitude and inverted phase, which gives rise to the standing wave observed in Fig. 1b. The acoustic power generated by a loudspeaker is equal to the time-averaged product of its volume velocity and the acoustic pressure on the cone surface. The fact that the acoustic pressure at the secondary source location is zero means that the secondary source can generate no acoustic power when operating to cancel the incident wave, and it acts as a purely reactive element. It is also possible to use an active control system to *absorb* the whole of the incident primary wave, instead of reflecting it back upstream, but such a strategy requires a pair of secondary sources.^{1,3}

2.2 Control of Multiple Modes

As the excitation frequency is increased, and the acoustic wavelength becomes comparable with the dimensions of the duct cross section, it becomes possible for more than just plane acoustic waves to propagate in the duct. The other types of acoustic field that can propagate in the duct have pressure distributions that are not uniform across the cross section of the duct and are referred to as higher order

modes. For a rectangular duct with a height L_y , which is greater than its depth L_z , the first higher order mode can propagate in the duct when it is excited above its first cuton frequency (also known as cutoff frequency) given by

$$f_1 = \frac{c_0}{2L_y} \quad (6)$$

If two identical secondary sources are used, one on either side of the duct, that are driven at the same amplitude, a plane wave will be produced when they are driven in phase; when they are driven out of phase, they will only excite the higher order mode. These two secondary sources can thus be used to excite any combination of amplitudes of these two modes and so could be used to actively control both modes. In general, it will require N secondary sources to control N modes, provided the combination of secondary sources is able to independently excite each of these modes.

Although it is, in principle, possible to actively control higher order modes using multiple secondary sources, there are several additional problems that are not encountered in the active control of plane acoustic waves, as discussed in more detail by, for example, Zander and Hansen.⁴ There is an increasing interest in the active control of higher order acoustic modes in short ducts because of the potential application in controlling the fan tones radiated from the inlet of aircraft engines, particularly as the aircraft is coming in to land. It should be noted, however, that the number of higher order modes that are able to propagate in a duct increases significantly with the excitation frequency, as illustrated in Fig. 2 for both a rectangular and a circular duct. The number of propagating modes is proportional to the square of the excitation frequency when it is well above the lowest cuton frequency. If

Figure 2 Number of acoustic modes that can propagate in a rectangular duct (solid line) or a circular duct (dashed line) as a function of excitation frequency, which has been normalized by the lowest cuton frequency of the duct, f_1 .

a significant amount of energy is being transmitted in each of these modes, then an active control system with a very large number of channels would be required to attenuate the overall pressure level at high frequencies. However, if it is only required to reduce the sound radiating at particular angles from the end of the duct, such as that which causes significant sound on the ground from an aeroengine inlet duct, this could be achieved by controlling a much smaller number of modes. It is possible to detect the amplitude of these modes using an axial array of sensors placed inside the duct.⁵

3 CONTROL OF SOUND RADIATION IN THE FREE FIELD

In the previous section, we saw that waves traveling in one direction could be either reflected using a single secondary source or absorbed using a pair of secondary sources. In this section we consider the active control of disturbances propagating as waves in three dimensions. The physical interpretation is clearest if we initially restrict ourselves to the control of waves propagating only away from the sources, that is, in infinite systems with no reflections. The waves propagating in such three-dimensional systems cannot be perfectly canceled unless the secondary source is physically collocated with the primary source. Significant reductions in wave amplitude can, however, still be achieved if the separation between primary and secondary sources is not too great compared with a wavelength. The total acoustic power radiated by the combination of sources provides a convenient way of quantifying the space-average or *global* effect of various control strategies. In this section we will introduce the idea of minimizing such a global measure of performance by adjusting the secondary source strengths, rather than arranging for the secondary sources to cancel the primary field perfectly.

In a mechanical system, the power supplied by a mechanical point force is equal to the time-averaged product of the force multiplied by the resultant velocity, but we must be more careful with acoustic sources since the force is a distributed quantity, determined by the acoustic pressure, and an acoustic source can also have a nonuniform distribution of velocity. However, if we assume that the source is vibrating with equal amplitude in all directions, such as a pulsating sphere, and that this sphere is small compared with the acoustic wavelength, so that the pressure on its surface is reasonably uniform, its power output can be simply calculated by taking the time-average product of the acoustic pressure at the surface and the volume velocity of the source.¹ The volume velocity q is equal to the radial surface velocity multiplied by the surface area. Such an acoustic source is known as a monopole. A practical example of such an acoustic source might be the end of an engine's exhaust pipe radiating sound at low frequencies, which could be the primary source in an active control system.

The relation between the complex acoustic pressure at a distance r from an acoustic monopole source

operating at a single frequency may be expressed as

$$p(r) = Z(r)q \quad (7)$$

where q is the complex volume velocity of the monopole source and $Z(r)$ is the complex acoustic transfer impedance. In an infinite medium with no acoustic reflections, that is, a free field, the acoustical transfer impedance is given by

$$Z(r) = \frac{\omega^2 \rho_0}{4\pi c_0} \left(\frac{je^{-jkr}}{kr} \right) \quad (8)$$

where ρ_0 and c_0 are the density and the speed of sound in the medium, and k is the acoustic wavenumber that is equal to ω/c_0 or $2\pi/\lambda$, where λ is the acoustic wavelength.

The time-average acoustic power generated by a monopole source is thus equal to

$$\Pi = \frac{1}{2} \text{Re}\{p^*(0)q\} \quad (9)$$

Using Eq. (7), this can be written as

$$\Pi = \frac{1}{2} |q|^2 \text{Re}\{Z(0)\} \quad (10)$$

where $\text{Re}\{Z(0)\}$ is the real part of the acoustical input impedance, which in a free field is given from Eq. (8) by

$$\text{Re}\{Z(0)\} = \frac{\omega^2 \rho_0}{4\pi c_0} \quad (11)$$

If an array of monopole sources is present, whose complex volume velocities are represented by the vector

$$\mathbf{q} = [q_1, q_2 \cdots q_N]^T \quad (12)$$

which generate complex pressures at each of these sources, represented by the elements of the vector

$$\mathbf{p} = [p_1, p_2 \cdots p_N]^T \quad (13)$$

then the total power radiated by the array of monopoles can be written as

$$\Pi = \frac{1}{2} \text{Re}\{\mathbf{p}^H \mathbf{q}\} \quad (14)$$

where the superscript H denotes the Hermitian or complex-conjugate transpose.

The pressure at each of the source positions depends on the volume velocity of each of the sources in a way that can be represented in matrix form as

$$\mathbf{p} = \mathbf{Z}_p \mathbf{q} \quad (15)$$

where \mathbf{Z} is the matrix of input and transfer acoustic impedances between the sources, which is symmetric since the system is assumed to be reciprocal.

The total radiated power can now be written as

$$\Pi = \frac{1}{2} \text{Re}[\mathbf{q}^H \mathbf{Z}^H \mathbf{q}] = \frac{1}{2} \mathbf{q}^H \mathbf{R} \mathbf{q} \quad (16)$$

where $\mathbf{R} = \text{Re}\{\mathbf{Z}\}$.

The vectors of source strengths and pressures can now be partitioned into those due to primary sources, \mathbf{q}_p and \mathbf{p}_p , and those due to secondary sources, \mathbf{q}_s and \mathbf{p}_s ,² so that

$$\begin{bmatrix} \mathbf{p}_p \\ \mathbf{p}_s \end{bmatrix} = \begin{bmatrix} \mathbf{Z}_{pp} & \mathbf{Z}_{ps} \\ \mathbf{Z}_{sp} & \mathbf{Z}_{ss} \end{bmatrix} \begin{bmatrix} \mathbf{q}_p \\ \mathbf{q}_s \end{bmatrix} \quad (17)$$

If we similarly partition the matrix \mathbf{R} as

$$\mathbf{R} = \text{Re} \begin{bmatrix} \mathbf{Z}_{pp} & \mathbf{Z}_{ps} \\ \mathbf{Z}_{sp} & \mathbf{Z}_{ss} \end{bmatrix} = \begin{bmatrix} \mathbf{R}_{pp} & \mathbf{R}_{ps} \\ \mathbf{R}_{sp} & \mathbf{R}_{ss} \end{bmatrix} \quad (18)$$

then the total radiated power can be written as

$$\Pi = \frac{1}{2} (\mathbf{q}_s^H \mathbf{R}_{ss} \mathbf{q}_s + \mathbf{q}_s^H \mathbf{R}_{sp} \mathbf{q}_p + \mathbf{q}_p^H \mathbf{R}_{sp}^T \mathbf{q}_s + \mathbf{q}_p^H \mathbf{R}_{pp} \mathbf{q}_p) \quad (19)$$

where $\mathbf{R}_{ps} = \mathbf{R}_{sp}^T$, because of reciprocity.

Equation (19) is of Hermitian quadratic form, as described by Nelson and Elliott,¹ so that the power is a quadratic function of the real and imaginary parts of each element of the vector \mathbf{q}_s . This quadratic function must always have a minimum rather than a maximum associated with it, since otherwise for very large secondary sources, the total radiated power would become negative, which would correspond to the impossible situation of an array of sources absorbing power from the otherwise passive medium. It is shown by Nelson and Elliott¹ that the minimum possible value of power is given by a unique set of secondary sources provided the matrix \mathbf{R}_{ss} is positive definite, and that this optimum set of secondary sources is given by

$$\mathbf{q}_{s,\text{opt}} = -\mathbf{R}_{ss}^{-1} \mathbf{R}_{sp} \mathbf{q}_p \quad (20)$$

The positive definiteness of \mathbf{R}_{ss} is guaranteed on physical grounds in this case since the power supplied by the secondary forces acting alone is equal to $\mathbf{q}_s^H \mathbf{R}_{ss} \mathbf{q}_s$, which must be positive for all \mathbf{q}_s , provided they are not collocated. The minimum value of the total power that results from this optimum set of secondary sources is given by

$$\Pi_{\min} = \frac{1}{2} \mathbf{q}_p^H [\mathbf{R}_{pp} - \mathbf{R}_{sp}^T \mathbf{R}_{ss}^{-1} \mathbf{R}_{sp}] \mathbf{q}_p \quad (21)$$

Each of the elements in the matrix \mathbf{Z} in Eq. (17) can be calculated by using Eq. (8), using the geometric arrangement of the primary and secondary forces to compute the distance between each of them. The maximum possible attenuation of the input power for this geometric arrangement of primary and secondary sources can thus be calculated by taking the ratio of the power before control, given by Eq. (19) with \mathbf{q}_s set to zero, and after control, Eq. (21).

The maximum attenuation in input power has been calculated for the arrangements of primary and secondary sources shown in Fig. 3a, in which a single primary source is controlled by one, two, four, or eight secondary sources each uniformly spaced at a distance d from the primary source. The results of such a calculation are shown in Fig. 3b, in which the attenuation for an optimally adjusted set of secondary sources is plotted against the separation distance normalized by the acoustic wavelength. A practical arrangement corresponding to this model problem may be the use of an array of loudspeakers used as secondary sources placed round the end of an engine's exhaust pipe in the open air.

When the separation distance is small compared with the acoustic wavelength, the attenuation achieved in radiated power for a single secondary source is large. The decrease of attenuation as the normalized separation distance increases is rapid, however. With a larger number of secondary sources attenuation can be achieved for greater separation distances. The general trend is that the number of secondary sources required to achieve a given attenuation increases as the *square* of the normalized separation distance d/λ . The maximum separation distance allowable between each of the multiple secondary sources to achieve 10-dB attenuation in total power output is about half a wavelength.

With a single layer of acoustic monopoles, all at equal distances from the primary source, the power output of the primary source can be reduced by reflecting the outward-going wave back toward the primary source. It can be shown that the power output of all the secondary sources is identically zero when controlling a single primary source,⁶ emphasizing their entirely reactive role; this case is thus directly analogous to the one-dimensional case whose pressure distribution is shown in Fig. 1b. It is also possible to use a double layer of acoustic monopoles, at unequal distances from the primary source, to *absorb* the waves radiated by the primary source. When operating in this manner, the pairs of monopole sources can be shown to be synthesizing a single point monopole/dipole source,¹ which is sometimes called a tripole.⁷

In practical applications, the sum of the squared pressures measured at microphones around the source array can be used as a measure of the radiated sound power. Multichannel control systems can be implemented to adjust the real and imaginary parts of the secondary source strengths to minimize this cost function, as described by Nelson and Elliott¹ and in more detail by Kuo and Morgan⁸ and Elliott.²

4 CONTROL OF ENERGY IN ENCLOSED SOUND FIELDS

One measure of the overall or *global* response of a finite system is the energy stored within it. In this section we discuss the active minimization of the acoustical energy in an enclosure. The energy stored in a system and the power supplied to it are related by the dissipation or damping in the system, since under steady-state conditions the power supplied to a system must increase its stored energy until the power lost

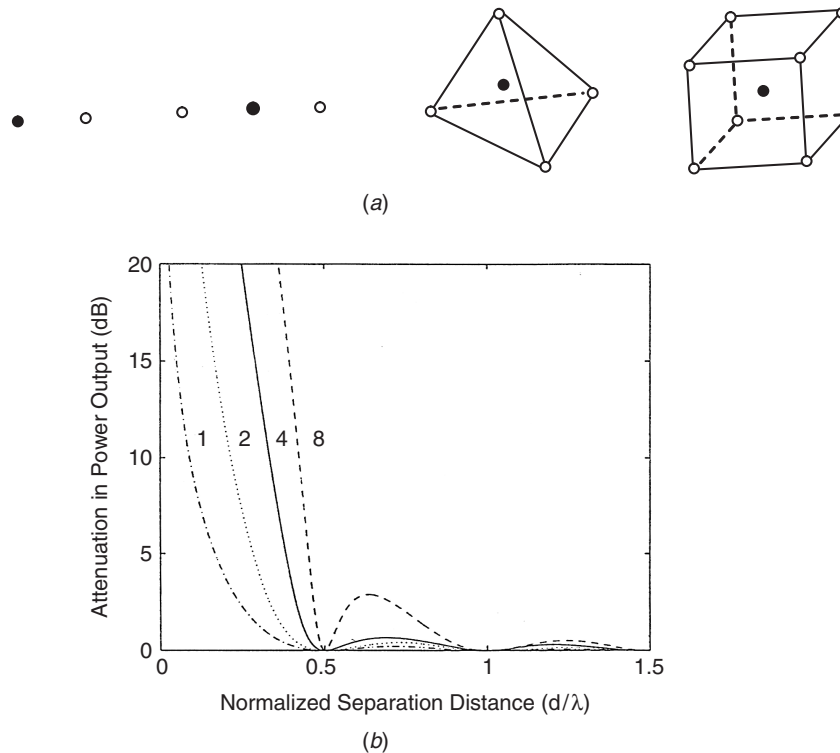

Figure 3 (a) Arrangement of primary (solid sphere) and secondary acoustic monopole sources (open spheres) in free space, used in the calculation of the attenuation of total power output. Each of the secondary sources is positioned a distance of d from the primary source. (b) Attenuation in the total acoustic power radiated into free space by a primary monopole source when optimally controlled by one (---), two (....), four (—), or eight (-.-) secondary monopole sources, as a function of the distance from the primary to the secondary sources, d , normalized by the acoustic wavelength.

through dissipation is the same as the power supplied by the sources. We would thus expect that if an active control system were adjusted to minimize the total power supplied to a system, the energy stored by the system would also be minimized. This turns out to be true in the majority of cases of practical interest, and although the minimization of total input power and total stored energy does give slightly different analytical results,² the differences are generally of academic interest rather than practical importance.

4.1 Control of Acoustic Energy in an Enclosure

The total acoustic potential energy, E_p , provides a convenient cost function for evaluating the effect of global active control of sound in an enclosure. Because of the assumed orthonormality of the acoustic modes, E_p is proportional to the sum of the squared mode amplitudes, and these mode amplitudes can be expressed in terms of the linear superposition of the contributions from the primary and secondary sources. Thus the total acoustic potential energy is a Hermitian quadratic function of the complex strengths of the secondary acoustic sources, which can be

minimized in exactly the same way as described in Section 3.

The result of simulation of minimizing the total acoustic potential energy in an enclosure of dimensions $1.9 \times 1.1 \times 1.0$ m, as shown in Fig. 4a, is illustrated in Fig. 4b. The acoustic modes have an assumed damping ratio of 10%, which is fairly typical for a reasonably well damped acoustical enclosure such as a car interior at low frequencies. The acoustic mode shapes in a rigid-walled rectangular enclosure are proportional to the product of three cosine functions in the three coordinates. The lowest order mode, with all n 's set to zero, has a uniform mode amplitude throughout the enclosure and corresponds to a uniform compression or expansion of the air at all points. The mode with the next highest natural frequency corresponds to fitting a half wavelength into the longest dimension of the enclosure. This first axial mode has a natural frequency of about 90 Hz for the enclosure shown in Fig. 4a, which is similar in size to the interior of a small car.

Figure 4b shows the total acoustic potential energy in the enclosure when driven only by the primary source placed in one corner of the enclosure and when the total acoustic potential energy is minimized by

Figure 4 (a) Physical arrangement for the simulation of the active control of tonal sound in a rectangular enclosure, which is about the size of a car interior, excited by a primary acoustic source in one corner and a secondary acoustic source in the opposite corner. (b) Total acoustic potential energy in the enclosure when driven by the primary acoustic source alone at discrete frequencies (solid line) and when the total potential energy has been minimized using either the single secondary source shown in (a), optimally adjusted at each excitation frequency (dashed line), or seven secondary acoustic sources placed in all the corners of the enclosure not occupied by the primary source (dash-dot line).

a single secondary acoustic source in the opposite corner (broken line) or by seven secondary acoustic sources positioned at each of the corners of the enclosure not occupied by the primary source (dash-dot line). Considerable attenuations in the total acoustic potential energy are achieved with a single secondary source below about 20 Hz, where only the zeroth-order acoustic mode is significantly excited and for excitation frequencies close to the natural frequency of the first longitudinal mode at about 90 Hz.

The response of the system does not, however, show clear modal behavior for excitation frequencies above about 150 Hz, and very little attenuation can be achieved with a single secondary source above this frequency. This is because the spacing of the natural frequencies of the acoustic modes in a three-dimensional

enclosure becomes smaller with higher mode order. Even introducing seven secondary sources into the enclosure does not allow global control to be achieved at frequencies above about 250 Hz in this case.

The amplitude of an individual mode of a physical system could be completely controlled using a single secondary source, provided it was not placed on a nodal line. In controlling this mode, however, the secondary source will tend to increase the excitation of other modes of the system. The minimization of total energy generally involves a balance between canceling the dominant modes and not overly exciting the other, residual, modes of the system. This balance is automatically maintained when the total energy in the system is minimized. The attenuation obtained in the energy at any one excitation frequency will generally depend on the number of modes that contribute substantially to the response.

4.2 Effect of the Modal Overlap

The number of modes that are significantly excited in a system at any one excitation frequency can be quantified by a dimensionless parameter known as the *modal overlap*, $M(\omega)$. This is defined to be the average number of modes whose natural frequencies fall within the half-power bandwidth of any one mode at a given excitation frequency ω . $M(\omega)$ is equal to the product of the modal density (average number of modal natural frequencies per hertz) and the modal bandwidth (in hertz), and both of these quantities can be calculated for the structural modes in a panel and the acoustic modes in the enclosure used in the simulations above.

For a three-dimensional rectangular enclosure, an approximate expression for the acoustic modal overlap can be calculated from that for the modal densities¹ as

$$M(\omega) = \frac{2\zeta\omega L}{\pi c_0} + \frac{\zeta\omega^2 S}{\pi c_0^2} + \frac{\zeta\omega^3 V}{\pi^2 c_0^3} \quad (22)$$

where L is the sum of the linear dimensions of the enclosure, S is its total surface area, V is the volume of the enclosure, ζ is the damping ratio, and c_0 is the speed of sound. At high frequencies the acoustic modal overlap increases as the cube of the excitation frequency. The modal overlap calculated for the acoustic modes in the enclosure shown in Fig. 4a is plotted in Fig. 5. In this case the modal overlap is less than unity for excitation frequencies below about 150 Hz, which was the limit of global control with one source in Fig. 4b, and is under seven for excitation frequencies below about 250 Hz, which was the limit of global control with seven sources in Fig. 4b.

The modal overlap can thus be seen to be a useful method of characterizing the complexity of the modal structure in a system at a given excitation frequency. It can also be used as a very approximate guide to the number of secondary sources required to achieve a given level of global control, that is, a given reduction in energy level in a system. The difference between the variation of modal overlap with frequency of a panel, shown dashed in Fig. 5, and of an acoustically excited enclosure, helps to explain the significant difference in

Figure 5 Modal overlap, $M(\omega)$, for the structural modes on a plate and for the acoustic modes in the enclosure used for the simulations shown in Fig. 4b (solid line).

the physical limitations of active control in these two cases.

The total acoustic potential energy in an enclosure is proportional to the volume integral of the mean-square pressure. In a practical active control system, the total potential energy can be estimated using the sum of the squared outputs of a number of pressure microphones. The number of microphones required to obtain an accurate estimate of the total acoustic potential energy is proportional to the number of substantially excited acoustic modes within the enclosure and thus increases sharply at higher excitation frequencies.

5 LOCAL CONTROL OF SOUND

Apart from minimizing a global cost function, such as radiated power or total energy, an active control system can also be designed to minimize the local response of a system. The physical effect of such a local control system will be illustrated in this section by considering the cancellation of the pressure at a point in a room.

5.1 Cancellation of Pressure in a Large Room

Cross sections through the acoustical zones of quiet, generated by canceling the pressure at a point in a large three-dimensional space, are shown in Fig. 6. The sound field in the room is assumed to be diffuse, which occurs when the excitation frequency is such that the modal overlap in Eq. (22) is well above unity. In this case, when the distance from the secondary source to the cancellation point is very small compared with the acoustic wavelength, the zone of quiet forms a *shell* around the secondary source, as indicated by the shaded area in the two-dimensional cross section shown in Fig. 6a. If the pressure is canceled in the near field of an acoustic monopole source, the secondary field will only be equal and opposite to the primary field at distances from the secondary source that are about the same as the distance to the cancellation point, thus generating a shell of cancellation. At higher frequencies, when the distance from the secondary source to the cancellation point is not small compared with the wavelength, then the zone of quiet does not form a complete shell round the secondary source but is now concentrated in a sphere centered on the cancellation point, whose diameter is about $\lambda/10$,⁹ as shown in Fig. 6b.

Figure 6 Cross section of the spatial extent of the acoustical "zone of quiet" generated by canceling the pressure at $x = L$ in a three-dimensional free field using a point monopole acoustic secondary source at the origin of the coordinate system for (a) $L = 0.03\lambda$ and (b) $L = 0.3\lambda$, where λ is the acoustic wavelength. The shaded area line corresponds to a 10-dB attenuation in the diffuse primary field.

The advantage of a local control system is that the secondary source does not have to drive very hard to achieve control because it is very well coupled to the pressure at the cancellation point. Thus local zones of quiet can often be generated without greatly affecting the overall energy in the system. Local active control systems also have the advantage that, because the secondary actuator and the error sensor are close together, there is relatively little delay between them, which can improve the performance of both feedforward and feedback control systems. One of the earliest designs for a local active control system was proposed by Olsen and May,¹⁰ who suggested that a loudspeaker on the back of a seat could be used to generate a zone of quiet round the head of a passenger in a car or an aircraft. Olson and May¹⁰ had the idea of using a feedback control system to practically implement such an arrangement, although in the 1950s most of the design effort had to be spent in reducing the phase lag in the audio amplifier to ensure stability of the feedback loop. More recent investigations of such systems¹¹ have demonstrated the trade-off in such a system between good acoustic performance and robust stability of the feedback loop.

The upper frequency of control in such a system will be fundamentally determined by the acoustical considerations outlined above, and the extent of the listener's head movements. Zones of quiet of a useful size can be achieved in practice up to several hundred hertz. The obvious extension to such a local control system would be to arrange for the loudspeakers to move with the ears, as in an active headset. Under these conditions the entrance of the ear canal is kept very close to the position of the loudspeaker, and the fundamental acoustical limitations discussed above can generally be avoided up to a frequency of about 1 kHz. The main features of an active headset are illustrated in Fig. 7, in which an analog feedback controller is used to control the low-frequency pressure at a microphone located close to the ear. A well-designed headset will have good sound attenuation at high frequencies, and the low-frequency enhancement in the attenuation by the active system complements this passive performance at higher frequencies.

6 CONCLUSIONS

The physical principles of active sound control are most easily illustrated by the one-dimensional problem of plane waves propagating in a duct. A single secondary source can be used to reflect an incident primary plane wave and a pair of secondary sources can be used to absorb an incident plane wave. At higher frequencies, multiple waves can propagate in the duct and multiple actuators then need to be used to control the transmission of acoustic energy.

An electrical controller is required to drive the secondary acoustic source, and this can either take the form of a feedback controller or an adaptive feedforward controller if prior information about the primary field is available.² Although the principles of active noise control have been known since the 1930s¹² and significant advances were made in the 1950s,^{10,13}

Figure 7 Active headset in which the sound inside the headset is detected by the microphone and typically fed back via an analog controller to the loudspeaker to reduce the low-frequency sound pressure level.

it was not until the development of economical digital signal processing (DSP) devices in the 1980s that large-scale problems were practical. Apart from active headsets, current applications include the active control of sound in ducts, inside propeller aircraft,¹⁴ and inside cars.¹⁵

The problem of spatial matching becomes more severe when secondary acoustic sources are used to attenuate the sound power output of a primary source in a three-dimensional space. If the sources are in the free field, a single monopole secondary source must be spaced within about one tenth of an acoustic wavelength of a monopole primary source if reductions of 10 dB are to be achieved in sound power output. If multiple secondary sources are used, the number of secondary sources necessary to obtain a given level of performance increases with the square of their distance from the primary source.

When the primary source drives an enclosed sound field, a number of different active control strategies may be used. These strategies can be illustrated most easily by returning to the one-dimensional field in a duct as discussed by Elliott,² which is closed at the two ends by the primary and secondary sources. Canceling the pressure in front of the secondary source effectively changes the end condition in the duct from open to closed; resonances are still apparent but are shifted in frequency. Driving the secondary source so as to absorb the incident sound wave suppresses these resonances. However, the most effective strategy for reducing the stored energy in the enclosure is to drive the secondary source so as to minimize the total power input to the duct from both the primary and secondary sources. This strategy maintains the sound field in an

antiresonant condition at each frequency and is almost equivalent to minimizing the total acoustic potential energy in the enclosure, giving significant reductions in the stored energy at each of the resonant frequencies.

The number of modes of a three-dimensional enclosure that are significantly excited at a given driving frequency well above the first natural frequency increases with the cube of that frequency, and a single secondary source is not sufficient to control such a sound field above the first resonance frequency. Multiple secondary sources can be used to achieve control in this case, provided there are at least as many secondary sources as significantly excited acoustic modes. By using an array of microphones, a practical approximation to the total acoustic potential energy can be measured in an enclosure, which can be used to automatically adjust the amplitude and phase of the multiple secondary sources to minimize this quantity.

Such a control system with 16 loudspeakers and 32 microphones was used in the original demonstration of the control of propeller noise in a passenger aircraft.¹⁶ Commercial systems are now available for this purpose, although more recent systems use electromagnetic shakers attached to the fuselage as actuators instead of loudspeakers, which can control the vibration in the passenger cabin as well as the noise.^{14,17}

Finally, the possibility of operating an active control system at higher frequencies is considered, by controlling only the local sound field around a person's head instead of the global sound field throughout an enclosure. It is shown that such a strategy can generate a zone of quiet that forms a shell round the secondary source at low frequencies. At high frequencies the quiet zone reduces, on average, to a sphere centred on the cancellation microphone, whose diameter is one tenth of an acoustic wavelength. Unless this zone of quiet can always be maintained close to the ear, as in the case of an active headset, degradation due to the natural movement of a listener's head will restrict the frequency range of a headrest system using such local active control to frequencies below a few hundred hertz.

Active control techniques are thus seen to complement conventional passive control methods since they are most effective at low frequencies. Current applications are mainly in the aerospace field, where the reduced weight of an active system for low-frequency noise control, compared with a passive one, is worth the additional cost and complexity of an electronic system.

CHAPTER 64

ACTIVE VIBRATION CONTROL

Christopher Fuller

Department of Mechanical Engineering
Virginia Polytechnic Institute and State University
Blacksburg, Virginia

1 INTRODUCTION

Passive vibration control methods work well at high frequencies or in a narrow frequency range but often have the disadvantage of added weight and poor low-frequency performance. Active vibration control has demonstrated the potential to solve many of these problems. Although the potential of active vibration control has been well known for many years, recent advances in fast digital signal processing computer chips have made these systems realizable.

In active vibration control secondary vibration inputs are applied to the structure to modify its response in a desired manner. The major components of an active vibration control system are the plant, actuators, sensors, and a controller. The plant represents the physical system to be controlled. Error sensors are needed to measure the system response while control actuators provide the necessary inputs to the plant to modify its response. The controller implements the chosen control algorithm to ensure that the controlled (or closed-loop) system behaves as required. The closed-loop system consists of the open-loop (uncontrolled) system dynamics combined with the dynamics of the controller and thus behaves in a modified form. Examples of practical active vibration control systems include active engine supports in vehicles and active vibration isolation systems for propeller aircraft.

2 CONTROL ACTUATORS

The arrangement of an active control system is usually based upon the physics of the system to be controlled and thus, as illustrated below, is often application dependent.¹ There are many texts on active control of vibration, mainly focused on the control theory. The text by Meirovitch² provides an excellent theoretical basis while the text of Fuller et al.³ describes in detail both feedforward and feedback control theory, actuators and sensors, as well as many relevant applications. Chapter 63 also discusses the related area of active noise control. It should be noted that active control is not a panacea for every vibration problem, and its application should be chosen with care depending upon a number of important characteristics such as the temporal nature of the disturbance, the spatial nature of the noise field, and the dynamic characteristics of the disturbance.⁴

Actuators are used to introduce control forces into the plant to modify its behavior, and their design/selection (in conjunction with the sensors) is

often the most important step in an active noise control project. Actuators can take various forms that are dependent upon system requirements such as the required control authority (amount of control force, moment, strain, or displacement), power frequency response, and physical constraints such as size, mounting requirements, and so on. Actuators are generally classified into two main categories: *fully active* actuators that apply a secondary vibrational response to the structure (i.e., can add energy to the structure) and *semiactive* actuators that are passive elements and can be used to adaptively adjust the mechanical properties of the system (i.e., do not add energy to the structure).

2.1 Electrodynamic Actuators

Electrodynamic actuators or shakers consist of a moving wire coil mounted inside a permanent magnet. As they are readily available and their behavior is relatively well understood (see Ref. 5 and Chapters 5 and 37), electrodynamic shakers are presently the most common control input as a fully active device. They are usually installed by either attaching directly to the structure by a stinger or placing in series or parallel with passive mounts, as in the case of active isolation (see Section 5). While electrodynamic actuators have the advantage of relatively large control displacement, they are usually bulky and require some form of support structure. However, there are many applications at low frequencies in which their use is more than adequate. Electrodynamic actuators are usually modeled in terms of control inputs as point forces, and they are thus “spectrally white” in terms of the spatial wavenumber response of the excited structure.

Typical structural components encountered in practice can often be simply represented as beams or plates. The transverse vibration displacement w of a simply supported thin plate excited by a point force $F e^{i\omega t}$ is described by⁶

$$w(x, y, t) = \frac{-4F}{M} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{\sin(m\pi x_f/L_x) \sin(n\pi y_f/L_y) \sin(m\pi x/L_x) \sin(n\pi y/L_y) e^{i\omega t}}{\omega^2 - \omega_{mn}^2 + i2\zeta_{mn}\omega\omega_{mn}} \quad (1)$$

where the force is located at (x_f, y_f) , ω_{mn} is the natural frequency of the (m, n) th mode, and M is the total mass of the plate. In Eq. (1), L_x and L_y are the transverse dimensions of the plate, x and y

are axial coordinates, ω is the frequency of excitation, and ζ_n is the modal damping ratio. Response of other more complex systems to point forces can be found in well-known texts such as Ref. 6.

2.2 Piezoelectric Actuators

As discussed in Ref. 7, piezoelectric transducers consist of material that expands or contracts when an electric field is applied over it. By applying an oscillating voltage to the piezoelectric element, its strain can be made to oscillate the same frequency as the input. Three major types of piezoelectric material are readily available: (1) a ceramic form such as PZT (lead zirconate titanate), which has relatively high control strain but is brittle; (2) a polyvinyl form such as a PVDF [polyvinylidene difluoride], which is flexible but has less control strain for the same configuration; and (3) a piezoelectric rubber, which is useful for underwater applications. Piezoelectric material is configured in the two main forms of *stack* and *wafer*, as shown in Fig. 1. Piezoelectric stacks are configured so that when a voltage is applied across the electrodes, the stack usefully expands in its long or 3–3 axis.⁷ Stack arrangements such as Fig. 1 are thus suitable for actuators in vibration isolation in the two

configurations of parallel and series shown in Figs. 1a and 1b.

For a given applied voltage V the net static displacement δ of the piezoelectric ceramic actuator shown in the parallel configuration of Fig. 1a can be calculated from

$$\delta = \frac{d_{33}V + F/K_a}{1 + K/K_a} \quad (2)$$

where d_{33} is the strain constant of the piezoelectric material in the 3–3 axis,⁷ K is the external spring stiffness, K_a is the actuator stiffness ($K_a = E_a A_a / L_a$, where L_a , A_a , and E_a are the actuator length, cross-sectional area, and Young's modulus, respectively); F is the external load force. Note Eq. (2) can be used as the basis of an approximate dynamic analysis, as discussed in Ref. 3. The significant advantage of the piezoelectric stack is that it can provide high force; however, its displacement is limited (relative to electrodynamic actuators), which, as discussed later, implies that its use is primarily in series-active isolation implementations.

The other common form of piezoelectric actuator is the wafer arrangement shown in Fig. 1c. In this form the transducer usefully strains in its thin transverse axis

Figure 1 Piezoelectric actuator configurations: (a) stack in parallel, (b) stack in series, and (c) collocated wafer.

(3–1 or 3–2) when a voltage is applied across the electrodes. The wafer is usually bonded or embedded directly into the structure and actuates the structure by applying surface or interior strains. Figure 1c shows piezoelectric elements arranged to create pure bending. In this configuration the elements are wired 180° out of phase so that as one element expands, the other contracts. As discussed in Ref. 8, the surface-mounted collocated actuator with a perfect bonding layer (which is a good approximation if the glue layer is thin) effectively applies a line moment to the structure at the boundaries of the actuator.

For a two-dimensional patch system in spherical bending of a plate, the effective moments m_x, m_y of the actuator are given by⁹

$$m_x = m_y = \frac{-E_p(1 + \nu_{pe})}{3(1 - \nu_p)} \frac{2P'h^2\epsilon_{pe}}{(1 - \nu_p - (1 + \nu_{pe})P')} \quad (3)$$

where

$$P' = P \frac{1 - \nu_p^2}{1 - \nu_{pe}^2} \quad (4)$$

In Eqs. (3) and (4) ν_{pe} and ν_p are the Poisson's ratio of the piezoelectric and the plate material, respectively, while E_b and E_{pe} are the Young's elastic modulus of the beam material and piezoelectric element, respectively, while h is the half thickness of the beam, t is thickness of the piezoelectric element, V is the applied Voltage, and d_{31} is the piezoelectric transverse strain constant. The constant P can be found in Ref. 9. More information of piezoelectric elements and their properties as well as definitions of important terms can be found in Ref. 7. Excitation of plate and beam structures with piezoelectric patches is discussed in Refs. 9 and 10, respectively. Piezoelectric actuators can be used either in a semiactive or a fully active form.

2.3 Advanced Actuators

The desire for an optimum actuator has stimulated development of new materials and configurations. The requirements, depending upon application, are typically high force and/or displacement, large bandwidth of operation, lower power consumption, and ease of use.

Shape memory alloy (SMA) shows much potential for high-force actuation at direct current (dc) to very low frequencies. The mechanism by which SMA fibers or films exhibit their characteristic shape memory effect can be described very basically as follows: An object in the low-temperature martensitic condition, when plastically deformed and the external stresses removed, will regain its original (memory) shape when heated. The process is the result of a martensitic phase transformation taking place during heating. When SMA is heated through its transformation temperature, the elastic modulus of the material changes dramatically, and if the material is initially stretched, it will shrink back to its original size. If the SMA is constrained during this procedure, very high

restoring forces are generated. More information on SMA can be found in Ref. 11.

The SMA systems are usually configured by embedding the material in a structure in a similar manner to layups of composite structures. It can be activated in a steady-state manner, applying steady-state in-plane forces that can be used to tune the resonant frequencies or change the mode shapes of the system (i.e., as semiactive actuator).¹² Over a very limited frequency range it can be used as an oscillating control input (i.e., a fully active actuator) by positioning the SMA off the central axis of the structure and driving with an oscillating voltage.¹² The advantage of the SMA is the extremely high force and deflection that it can provide at very low frequencies. Disadvantages are high power consumption, a need for heat dissipation, and a limited frequency response, which depends entirely upon the cooling rate. Use of SMA in the control of transient vibration of a cantilevered beam as well as sound radiation control is discussed in Ref. 12.

Magnetorestrictive materials also show much possibility as advanced fully active actuators in that they fill the performance gap between low-force, high-displacement electromagnetic actuators and high-force, low-displacement piezoelectric devices. A typical actuator using the material Terfenol-D and approximately 11 cm in length and 5 cm in diameter can produce forces in excess of 450 N over a frequency range of 0 to 2.5 kHz.¹³ However, the power requirements tend to be somewhat higher than electrodynamic and piezoelectric devices.

Electrorheological (ER) fluids are suspensions of highly polarized fine particles dispersed in insulating oil.¹⁴ The viscosity and the elasticity of the ER fluid can be changed several orders of magnitudes when an electric field is applied to the medium. The ER fluid can thus be embedded in structural systems and used as a "semiactive" actuator to tune the system's properties such as damping and stiffness by varying the voltage applied to the ER fluid.¹⁵

3 ERROR SENSORS

Error sensors are employed to measure the motion of the system to be controlled. This information either is used directly as the variable(s) to be minimized or is used to calculate a related state for the system to be controlled. Sensors come in three main forms: point sensors, arrays of point sensors, and distributed sensors. Choice of the particular configuration is dependent upon the system variable to be controlled, as discussed below.

3.1 Accelerometers, Force Transducers, and Impedance Heads

Accelerometers are commonly used as error sensors due to the ease of use and reliability of performance. Their implementation and behavior is discussed in more detail in Chapter 37. When attached to a vibrating structure, they can provide estimates of the time-varying acceleration (as well as velocity and displacement with signal processing) at the

point of attachment. Due to their small size, at low frequencies accelerometers provide a point sampling of the structural motion and thus are “spectrally white” in wavenumber response. Thus an individual accelerometer will equally sense all structural wavenumber or modally weighted contributions. Use of an accelerometer output as an error signal will result in direct control of the structural motion at that point.

Force transducers can also be used as error sensors, particularly in applications such as active isolation, where they may be placed in series with passive isolation. Minimization of the force transducer output will result in zero dynamic force being applied to the receiving structure. The point input impedance of a structure, such as at a disturbance location, can be estimated using an impedance head that consists of a collocated accelerometer and force transducer. The output of the impedance head can then be used as a narrow-band error sensor variable to minimize the real part of the structural input impedance and thus disturbance input power flow into the structure.

Choice of one of the above transducers as an error sensor is dependent upon the form of application. This will be illustrated in the later example applications.

3.2 Arrays of Point Sensors

Usually it is more effective to use accelerometers as error sensors in an array configuration whose output signal is processed to provide some global or distributed state associated with the system.

The *kinetic energy* of a thin vibrating system can be minimized by using a distributed array of accelerometers positioned over the required controlled domain. An estimate proportional to out-of-plane kinetic energy of the structure is given by

$$E = \sum_{i=1}^N |\dot{w}_i|^2 \quad (5)$$

where N is the total number of accelerometers and \dot{w} is the out-of-plane velocity obtained by integrating the acceleration signal. The variable E can be minimized, or if an N -channel controller is available, each accelerometer can be used as an individual control channel. The required number and spacing of accelerometers are determined by the Nyquist sampling criterion applied in the spatial domain: Two accelerometers must be spaced within at least a half-wavelength of the highest mode required to be observed and controlled. Alternatively, the accelerometers can be appropriately distributed throughout the surface whose global motion is to be controlled. Use of a lower number of accelerometers (relative to the number of actuators) often leads to large minimization at their locations but increased levels of vibration at other locations. This effect is termed control spillover. In general, to ensure controllability, a system state or mode has to be individually observed.

Wavenumber components of structural motion can be obtained using arrays of equispaced accelerometers

arranged along a coordinate axis. The spatial one-dimensional Fourier transform can be approximated using a discrete Fourier transform such as³

$$\hat{W}(k) = \sum_{n=1}^K w_m(x_n) e^{ikx_n} \Delta x \quad (6)$$

where $w_m(x_n)$ is the measured out-of-plane complex displacement at position x_n . In Eq. (6) there are N measurement points equally spaced at a distance Δx . Note Eq. (6) can also be expanded into a time-space transform if necessary and extended to two dimensions. The output of Eq. (6) can be used to provide an error signal. Minimization of spectral components $W(k)$ then will provide control of selected wavenumber values. For example, in a finite structure vibrating at a single frequency, the wavenumber components will be discrete and associated with particular modes or waves traveling in the positive or negative directions. In many situations it is appropriate to control these components directly.

Modal decomposition of the structural motion is also a useful processing technique. To achieve this, an array of accelerometers is used to measure out-of-plane motion at a number of points. Thus, knowing the structural mode shapes and using a pseudoinverse technique, the modal amplitudes can be estimated from¹⁶

$$[A] = ([L]^T [L]^{-1}) [L]^T [w_{me}] \quad (7)$$

where $[A]$ is a vector of m unknown modal amplitudes and $[w_{me}]$ is a vector of n measured displacements at (x_n, y_n) . In Eq. (7) $[L]$ is an $n \times m$ matrix associated with the mode shapes Ψ of the system defined as

$$[L] = \begin{bmatrix} \Psi_1(x_1, y_1) & \Psi_2(x_1, y_1) & \cdots & \Psi_m(x_1, y_1) \\ \vdots & & \ddots & \\ \Psi_1(x_n, y_n) & & & \end{bmatrix} \quad (8)$$

Equation (7) can also be readily modified to decompose narrow-band traveling-wave fields into individual wave components and can be implemented for broadband random disturbances, as outlined in the work of Gibbs et al.¹⁷ Equation (10) can thus provide indirect error information of a global nature associated with each mode. Minimization of a modal estimate will ensure that a particular mode is globally controlled in a vibrating structure. This is of use when particular modes are more important than others in a control strategy.

Kalman filtering techniques are used extensively in linear quadratic (LQ) control problems,³ where all the internal state variables of the system to be controlled must be known. Arrays of accelerometers can be used in conjunction with Kalman filtering to determine the states of the systems. When all the states are not measurable, they have to be estimated

using a mathematical model of the dynamic system and measurements of the output is the optimal estimator that minimizes the variance of the estimation error.¹⁸

Power flow can be estimated from an array of accelerometers mounted on the structure. For the simplest case of traveling bending waves on a thin beam, the net narrow-band bending power flow can be calculated by using two measurement points and finite difference theory as described in Ref. 19:

$$P(\omega) = \frac{2EI k_f^2}{\Delta x \omega^3} \text{Im}(S_{21}) \quad (9)$$

In Eq. (9) k_f is the flexural wavenumber at frequency ω ,⁶ Δx is the spacing of the two acceleration measurement points, and S_{21} is the cross spectrum between the output of the two accelerometers. Use of Eq. (9) as an error signal will thus result in minimization of net power flow in the structure in the vector direction of the alignment of the accelerometers. Extension of Eq. (9) to include near fields is also discussed in Ref. 19 (see also Chapter 16). As discussed above, it is also possible to decompose the motion of the structure into wave component amplitudes using a pseudoinverse technique. The power flow associated with each direction of propagation or wave type can be then estimated and used as an error signal. Using approaches such as these, it is possible to actively control termination impedances of beams.²⁰

3.3 Distributed Piezoelectric Sensors

Piezoelectric material, when strained from its free state, also creates a charge.⁷ Thus, when configured properly, piezoelectric material with attached electrodes to collect the charge can be used as an error sensor(s). The most common arrangement is to bond the piezoelectric material to one side of the surface of the structure whose motion is to be sensed. If the piezoelectric material is very thin, then it can be assumed that its presence has no effect on the motion of the structure. For a two-dimensional structure covered with a finite layer of piezoelectric material the charge output $q(t)$ of the sensor (in rectangular coordinates) can be calculated from the following²¹:

$$\begin{aligned} q(t) = (h_p + h_s) \int_S \Gamma(x, y) \\ \times \left[\epsilon_{31} \frac{\partial^2 w}{\partial x^2} + \epsilon_{32} \frac{\partial^2 w}{\partial y^2} \right. \\ \left. + 2\epsilon_{33} \frac{\partial^2 w}{\partial x \partial y} \right] dx dy \quad (10) \end{aligned}$$

where $w(x, y)$ is the plate out-of-plane response, $\Gamma(x, y)$ is the sensor shape function, h_p and h_s are the thickness of the plate and sensor, and ϵ_{31} , ϵ_{32} , and ϵ_{33} are the piezoelectric stress-charge coefficients where the subscripts 1, 2, 3, refer to the z , x , and y directions of a three-dimensional coordinate system.⁷ In effect, the piezoelectric material integrates the surface strain

of the structure over its area S (i.e., in the 1–2 plane) and thus provides continuous distributed sensing. The actual voltage output of the piezoelectric material is dependent upon the electrical circuitry used to measure the piezoelectric output. Shaped piezoelectric sensors are surface-mounted sensors that are of specified finite size and shape. Particular motions or modal components of the vibrating structure can be observed by cutting the piezoelectric material into a specialized shape. The charge output of an example rectangular piezoelectric strip mounted on a simply supported plate so that it extends completely over the plate in the x direction but is narrow in the y direction, is given by²²

$$\begin{aligned} q(t) = K \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{L_x L_y}{nm\pi^2} [\cos(m\pi) - 1] \\ \times \left[\cos\left(\frac{m\pi d}{L_x}\right) - \cos\left(\frac{n\pi c}{L_y}\right) \right] \quad (11) \end{aligned}$$

where L_x , L_y is the dimension of the plate in the x , y directions, K is a constant that modifies the charge output due to the external electrical load impedance, m and n are modal orders, and d and c are the vertical locations of the sensor boundaries in the y direction. Note Eq. (11) shows that for all even modes in the x direction ($m = 2, 4, 6, \dots$) the sensor output is zero. Thus the sensor acts as a spatial wavenumber or modal filter only observing odd modes in the x direction. Positioning and sizing of the piezoelectric strip can be adjusted to observe required modal or wavenumber components.

To observe individual particular modes of motion, the piezoelectric strip can be cut into a shape corresponding to a system characteristic function or mode shape.²¹ Thus, shaped sensors can provide a time-domain estimate of modal amplitudes of structural response, with minimal signal processing, in contrast to the previous method using arrays of accelerometers. However, once the sensor is shaped, its estimate is fixed, whereas the output of the accelerometer array can be manipulated by signal processing to observe various modes or waves.

The most commonly used piezoelectric sensing material is PVDF. It can easily be cut or etched into particular shapes. It is readily attached to the surface with double-sided tape or other means. Care must be taken to attach leads to the bottom of the element, and when the shaped sensor has phase changes throughout its segment each segment output should be wired together with the correct relative polarity to give the required sensor output. Note that matched shape piezoelectric material can be located on each side of a structure and the outputs either summed or differenced to selectively observe in-plane or bending motion, respectively.

4 CONTROL APPROACHES

The function of the controller is to process the error information received from the error sensors to calculate

Figure 2 Simple feedforward control arrangement.

control signals so as to cause the controlled or closed-loop system to behave in a required manner. Control approaches can be divided into two main categories: *feedforward* and *feedback* approaches, as discussed by Fuller et al.³

In general, feedforward control has found application when the designer has direct access to information about the disturbance signal to the system. On the other hand, feedback control has primarily been applied when the disturbance cannot be directly observed. In this case the control signals are obtained from the sensor(s) whose output is affected by both disturbance source and the control actuator(s). Chapter 63 also has relevant material on the active control paradigms discussed here.

4.1 Feedforward Control

Figure 2 presents a simple, illustrative arrangement of single-channel feedforward control; in this particular case the object is to minimize the vibration of a mechanical system at the error sensor, e . The most common form of electrical feedforward controller H is an adaptive finite impulse response (FIR) filter whose coefficients are updated by a control algorithm to drive the error signal to a minimum.

A critically important aspect of the feedforward approach is obtaining a reference or training signal that provides a coherent estimate of the disturbance signal and is “fed forward” through the adaptive filter to provide the control signal. The most commonly used update equation for dynamic systems is the time-domain Filtered X version of the Widrow-Hoff least-mean-squared (LMS) algorithm written in single-channel form as²³

$$w^i(n+1) = w^i(n) - 2\mu e(n)f(n) \quad (12)$$

where $w^i(n)$ is the i th coefficient of the adaptive filter at time n , μ is a convergence parameter, and $e(n)$ is the error signal at time n . The filtered reference signal $f(n)$ is given by

$$f(n) = \sum_{j=1}^P c^j x(n-j) \quad (13)$$

where c^j , $j = 1, 2, \dots, P$, are the weights of a fixed FIR digital filter that models the plant dynamics from

the actuator signal to the error signal and $x(n)$ is the reference signal taken directly from the disturbance. Equation (13) essentially accounts for the delay between the control system input and the error sensor output. The adaption of Eq. (12) also assumes no feedback of control signal to the reference signal. The fixed FIR filter is usually constructed before switching on the controller or with a low-level probe signal, as described in Refs. 3 and 4. In essence the Filtered X LMS algorithm is a gradient descent technique that finds the minimum of a quadratic cost function defined as the squared modulus of the error signal.

The choice of the filter format is dependent upon the noise disturbance. For a narrow-band signal it is necessary to use only two filter coefficients. Control of broadband signals require a larger filter in terms of coefficients, and causality aspects associated with relative delay through the control path become more important.³ The Filtered X algorithm can be readily extended to a multichannel configuration, as discussed in more detail in Ref. 24.

Note that the use of a reference signal estimate from the disturbance implies that the system will respond only to information coherent with the reference signal. The system will thus appear open loop to all other disturbances uncorrelated with the error signal. The maximum achievable attenuation of the power of the error signal for a single-input, single-output feedforward control arrangement can be calculated from^{3,4}

$$\Delta \text{dB} = -10 \log(1 - \gamma_{de}^2) \quad (14)$$

where γ_{de}^2 is the coherence between the disturbance and the error signals. If there is control signal feedback on the reference signals, then the feedback can be compensated for as described in Ref. 25.

Similar to the feedback control, it can be demonstrated that closed-loop systems under feedforward control have new eigenvalues and eigenfunctions²⁶ and that, for narrow-band disturbances, feedforward and feedback approaches are essentially equivalent.³ Due to convergence time requirements (the adaptive filter has to search for the minimum of the error surface), the feedforward algorithm does not presently work well with transients applied to nonmodeled systems but is suitable for pure tones or steady-state broadband signals. As the control filter is adaptive and “learns” the system by minimizing a cost function, it is not necessary to have an accurate model of the open-loop system behavior from the control actuator to the error sensor. For a single-channel time-domain controller applied at a single frequency, it is only required to estimate the fixed transfer function between the control input and error sensor within an accuracy of $\pm 90^\circ$ to ensure controller convergence.

The behavior of feedforward controlled systems can also be analyzed using linear quadratic optimal control theory. For the system of Fig. 2 a quadratic cost function is constructed by squaring the modulus of the error signal (or summing the squared modulus of the error signals). The optimal control input is found

by setting the gradient of the cost function to zero (i.e., at the minimum).

For a system with L error sensor the quadratic cost function is formed by summing the squared modulus of the error signals,

$$J = \sum_{l=1}^L |e_l|^2 \quad (15)$$

The optimal control inputs to minimize the cost function are found by setting the gradient of the cost function to zero, as described by Nelson and Elliott.²⁷ For a multiple-input, multiple-output arrangement the optimal vector q_{s0} of control inputs to minimize the cost function is specified by

$$q_{s0} = A^{-1} Z^H w_p \quad (16)$$

where Z is a matrix of complex transfer impedances relating the control force inputs to the response at the error sensors, the matrix $A = Z^H Z$ and w_p is the noise or primary complex field at the error sensors. More details on how to use Eq. (16) as well as calculating the minimum of the cost function can be found in Ref. 27. The above analysis is for a single-frequency, steady-state excitation and represents the maximum achievable performance. For random signals, the actual control performance will depend upon whether the control filters are physically realizable and other related issues, as described in Ref. 4.

4.2 Feedback Control

Figure 3 presents a typical arrangement of single-channel feedback control of motion of a general mechanical system. In this arrangement the control signal is derived from a sensor on the structure and is then “fed back” through a controller (or compensator) to provide a control input. The optimal controller is derived to perform a specified control task. Hence, generally speaking, for feedback control the system changes its dynamic characteristics for all disturbances applied to it, in contrast to the feedforward approach discussed previously.

Figure 3 Simple feedback control arrangement.

The open-loop equation of motion of a single-degree-of-freedom system excited by a disturbance force $f_p(t)$ can be written in the form³

$$m\ddot{w}(t) + c\dot{w}(t) + kw(t) = f_p(t) \quad (17)$$

where m , c , and k are the system mass, damping, and stiffness, respectively. For the mechanical system in Fig. 3 this may correspond to the response of one mode.

Extensions to distributed systems are described in Refs. 2 and 3. The open-loop transfer function (i.e., the ratio of the response to the disturbance) of this system can be evaluated using the Laplace transform³ and is given by

$$G(s) = \frac{W(s)}{F_p(s)} = \frac{1}{ms^2 + cs + k} \quad (18)$$

We now apply a secondary control force to the structure by feeding back a signal taken from the response of the system through a compensator with a transfer function K to drive the force $f_s(t)$. The closed-loop transfer function of the system with stiffness control, for example, is now given by

$$\frac{W(s)}{F_p(s)} = \frac{G(s)}{1 + G(s)K(s)} = \frac{1}{ms^2 + cs(K + k)s} \quad (19)$$

where s is the Laplace variable and K is the compensator gain or transfer function. Note that the closed-loop system effectively has a new effective stiffness $(K + k)$ and thus new poles.

For transient control the objective is often to increase the damping of the system. In this case the closed-loop poles are moved further into the left s -plane by varying the compensator gain K . However, an important aspect of feedback control is stability, which can be determined by inspection of the position of the closed-loop poles as described in Ref. 28. Too much compensator gain K , for example, can lead to an unstable control system. Often, in practice, the stability is assessed from input–output measurements made on the system before control. The Nyquist stability criterion is then applied to check if the system is stable, as described in Ref. 27. The outcome is that the closed-loop system is stable only if the polar plot of the open-loop frequency response function does not enclose the point $(-1, 0)$ in the complex Laplace plane s . Different forms of the compensator K to the simple example discussed above, can be chosen, depending upon the required control performance, and these are discussed in Ref. 3.

If it is possible to achieve a stable feedback system, then the error signal power is approximately reduced by an amount proportional to the loop gain,⁴ and the attenuation is given by

$$\Delta \text{dB} = -10 \log \left| \frac{1}{1 + GK} \right|^2 \quad (20)$$

Figure 4 Control force required for (a) direct, (b) opposed, and (c) parallel active vibration isolation systems.²⁹

In Eq. (20), $G(s)$ is the transfer function through the plant and $K(s)$ is the transfer function through the compensator.

In general, to calculate the optimal controller K , it is required to have an accurate model of the system to be controlled. This can be done through calculations such as finite element methods or more usually through estimates using system identification approaches as described in Ref. 3. Although multiple-input, multiple-output feedback control have a larger implementation requirement than feedforward control, it ensures that the system is controllable for all forms of linear noise disturbances if a realizable controller can be defined.

Extension of feedback control to multiple-input, multiple-output arrangements can be achieved using state space methods as outlined in Refs. 28 and 3. Other important factors affecting the performance and stability of feedback controllers are reviewed in Ref. 4.

5 EXAMPLE APPLICATIONS OF ACTIVE VIBRATION CONTROL

The following examples illustrate some of the wide diversity of present applications of active vibration control. Other implementations of active vibration control are discussed in Ref. 3.

5.1 Active Isolation of Vibration

A classic approach to reducing unwanted machinery noise and vibration is to control these disturbances at transmission bottle necks (e.g., the machinery mount). Active vibration isolation has been studied by a number of authors, as summarized in Ref. 3, and a few representative examples will be presented here.

There are four possible configurations for active isolation: The two most common are *series*, in which the actuator opposes the load path, and *parallel*, where the active force is applied in parallel with the load path. As discussed by Scribner et al.,²⁹ if the actuator

is placed in parallel, it must overcome the stiffness of the passive mount, and the actuator deflection requirements are relatively larger. If the actuator is in series, then while the deflection requirements are lower than the parallel implementation, the actuator must carry the load and, as will be seen below, the force requirements are higher. Two other, less common implementations are when the active force is directly applied to the exciting system and when the active or secondary force is applied directly to the receiving structure at the mount location. This latter implementation is termed opposed. Both of these latter implementations have the disadvantage of requiring some form of inertial exciter (e.g., an electrodynamic shaker that is provided with a mass against which it can react).

Figure 4 presents the magnitude of the ratio of the secondary control force f_{s0} to the primary disturbance force f_p required for a “parallel” and “opposed” implementation calculated by Nelson et al.³⁰ for a lumped-parameter single-degree-of-freedom mass–spring system. The nondimensional frequency $\Omega = \omega/\omega_n$, where ω_n is the natural frequency of the mass–spring system on a rigid base. Also shown is the relatively trivial case of when the control force is directly applied to the exciting mass and thus exactly equals the disturbance magnitude to drive the motion to zero. The results of the opposed case are similar in trend to the series implementation, which is discussed in much more detail in Ref. 31. The results show that at resonance the force requirements of the opposed system are much larger while below resonance the converse is true. Well above resonance the force requirements of both arrangements are similar. For control systems designed to operate near the plant resonance, the above characteristics usually imply that electrodynamic actuators (i.e., relatively large deflection, lower force) are used for the parallel implementation while piezoelectric ceramic actuators (i.e., relatively larger force, low deflection) are used for the series arrangement.

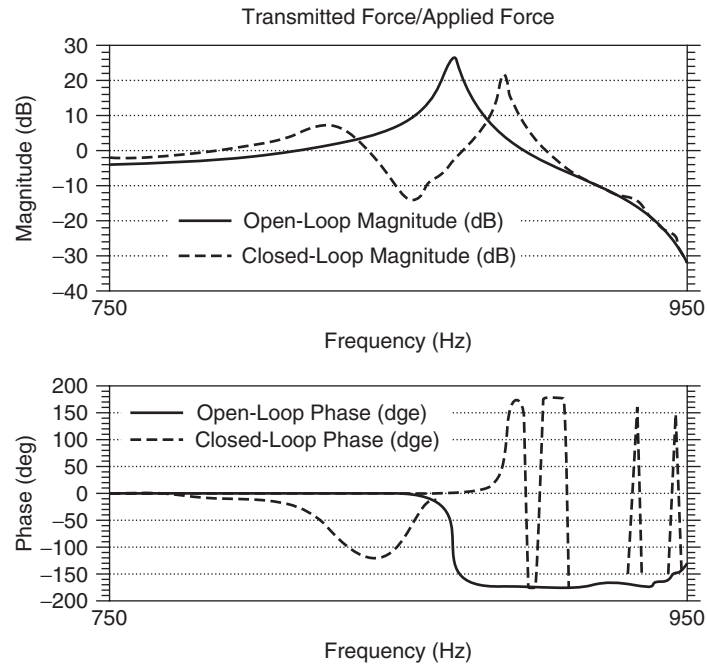

Figure 5 Performance of a series active vibration isolation system.²⁹

Scribner et al. have theoretically and experimentally studied the use of piezoelectric ceramic actuators in a “series” implementation of active isolation using a classical feedback approach²⁹ focused upon sinusoidal disturbances. Figure 5 presents typical values of open-loop and closed-loop behavior of the ratio of transmitted to applied force versus frequency. In this example the compensator natural frequency was set to 877 Hz and a large enhancement in transmitted force is observed near this design frequency. However, in the frequency range of $825 \leq f \leq 850$ Hz, high attenuation in the transmitted force is achieved. Scribner et al.²⁹ also demonstrated how the controller could be implemented in a self-tuning implementation so as to track a disturbance frequency, even through structural resonance.

Nelson et al.^{3,30} have also analytically and experimentally investigated narrow-band isolation of the vibration of a rigid raft from a flexible receiving structure using multiple active isolators configured in the parallel arrangement. In this case the active inputs were provided by four electromagnetic coil actuators used in conjunction with a multichannel adaptive LMS feedforward control approach. The error signals were taken from either four accelerometers located adjacent to the mount points or eight accelerometers distributed over the surface of the receiving structure. The results demonstrate that the use of eight accelerometers was more effective than four in attenuating the total energy of the receiving structure over much of the frequency range. This behavior illustrates the advantage in feedforward control of using more sensors than actuators; a

“square” feedforward control system with equal number of actuators and sensors will always try to drive the response to zero at the error sensors, and for high modal densities this can lead to “control spillover” or an increase in the response away from the error sensors. It is thus often beneficial to use more error sensors than actuators when global reduction is required. The results presented in Ref. 3 also show that the passive isolation (i.e., no active control) produced an increase in the receiving structure vibration at some of its resonance frequencies. This characteristic illustrates the importance of the receiving structure dynamics on the isolation performance.

Figure 6 shows a set of active isolation mounts fitted between the engine and frame of a Volkswagen Golf GTI. The system was developed and tested by Lotus Engineering.³² A feedforward controller was used to minimize the sum of the squared vibration amplitudes measured at four accelerometers. A reference signal was generated by the engine tachometer. Figure 7 shows the measured reduction in the “second-order” vibration levels due to the active engine isolation mounts as a function of engine speed without control (solid line) and with control (dashed line). Significant reduction has been clearly achieved.

5.2 Distributed Active Vibration Control of Plates

The control of vibration of distributed structural elements such as plates is also an important problem. Figure 8 is an experimental arrangement used

Figure 6 Active isolation mounts installed in a Volkswagen Golf GTI.³²

Figure 7 Measured attenuation of vibration due to active engine mounts of the system of Fig. 6.³²

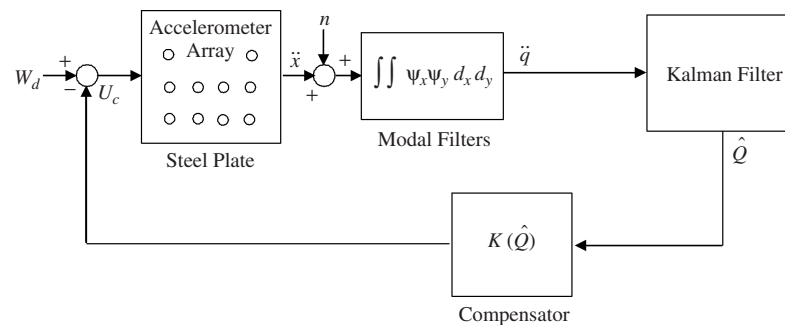

Figure 8 Linear quadratic Gaussian (LQG) feedback control system for active reduction of plate vibrations.³³

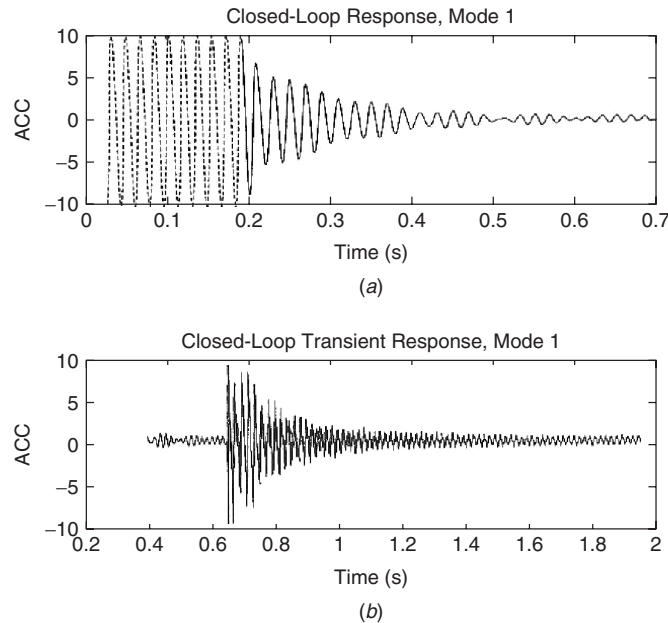

Figure 9 Closed-loop response of the system of Fig. 10 for mode 1 with (a) narrow-band steady disturbance and (b) transient disturbance at $t = 0.65$ s.³³

by Rubenstein et al.³³ to implement linear quadratic Gaussian state space feedback control³ of the vibration of a simply supported plate. The response of the system is sensed using an array of 12 accelerometers of the plate. The output of the accelerometers is passed through modal filters to obtain modal amplitudes and then through a Kalman filter to obtain the states of the system. The optimal controller $K(\hat{Q})$ can be obtained using a Riccati equation solution of the state space feedback control arrangement.³ In this experiment the steel panel was 0.6 by 0.5 m and 3 mm thick. The disturbance and control were implemented by electrodynamic shakers. Figure 9a shows a typical closed-loop response for mode 1 when the disturbance is narrowband, continuous excitation, while Fig. 9b gives closed-loop response to a transient disturbance applied at near $t = 0.65$ s. In both cases high modal attenuation of the disturbance is achieved. Thus state space feedback methods show much potential for distributed active vibration control a wide range of input disturbances. Note that state space feedback control implies complete control of specified states of the system as opposed to feedforward control, which usually controls a direct output of the plant at the error sensors (displacement, velocity, etc.). Thus global control of the system is guaranteed if all the dominant states are observed and controlled with no control spillover. This is often difficult to achieve in practical systems. As discussed previously, the state space approach also guarantees control of the system to a wide range of disturbances without requiring access to a reference signal.

Although state space approaches can achieve high performance, it is often achieved with a certain degree of complexity. Elliott et al.³⁴ have developed an alternative approach that uses arrays of independent feedback loops with collocated actuators and sensors. Figure 10 shows such an approach applied to the global reduction of vibration of a panel.

Since the actuator and sensors in the system of Fig. 10 are collocated, the feedback control approach is minimum phase, and thus each loop is theoretically independently stable. However, since all the feedback loops are coupled by the distributed dynamics of the panel (i.e., the control input of one loop will be sensed by the feedback sensors of the other loops), the control system will likely be unstable with a general feedback compensator design. To overcome this problem Elliott et al.³⁴ have restricted the compensator design to paradigms that do not add energy to the structure (each feedback gain is limited to positive sign). Under this limitation it can be proved that the multiple independent feedback loops are stable and in effect represent semiactive approaches.

Figure 11 shows example predicted results where 16 independent feedback loops with feedback gains of 10 (dashed line), 100 (dotted line), and 1000 (dot-dashed line). The vertical axis is the calculated total kinetic energy of the plate, and the feedback loops employ point force actuators and velocity sensors. The disturbance to the panel is an acoustic plane wave. The uncontrolled vibration is shown as a solid line. As the gain is increased, the resonances of the panel response are increasingly damped as one would expect

Figure 10 Multiple independent feedback loops used to control the global vibration of a panel.³⁴

Figure 11 Performance of multiple independent feedback loops used to control the global vibration of a panel.³⁴

with a velocity feedback paradigm. Note that if the gains are increased too much, then control spillover appears above 600 Hz due to additional modes with short wavelengths due to the panel being pinned at the feedback sensor locations. For moderate gains, the results of Fig. 11 demonstrate that multiple uncoupled collocated feedback loops can provide high global attenuation of vibration. Since the system is uncoupled, it is possible to implement the feedback loops in analog

form, and thus the physical control system hardware requirements and complexity are small.

5.3 Active Structural Acoustical Control

Vibrating structures often radiate or transmit unwanted sound. An effective technique to control the structural sound radiation is to apply control inputs directly to the structure while minimizing the radiated sound or components of structural motion associated with

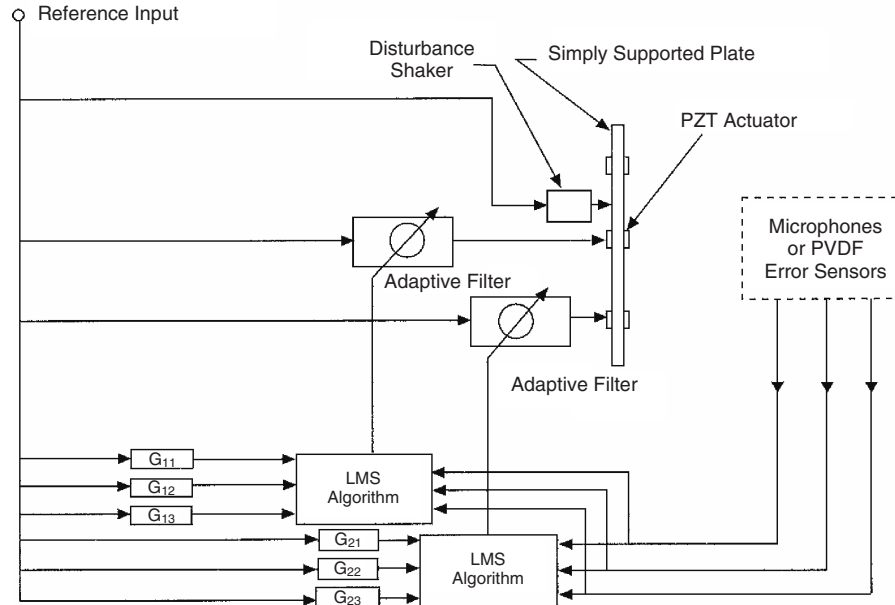

Figure 12 Experimental arrangement and control block diagram for active reduction of sound radiation from a plate (ASAC).²²

the sound radiation.^{3,35} The technique called active structural acoustical control (ASAC) thus falls in the class of general active vibration control techniques. Figure 12 shows an experimental arrangement in which the sound radiation from a simply supported plate is to be minimized.²² The noise disturbance is provided by a point force shaker attached to the plate and driven by a pure tone. The control inputs are multiple collocated piezoelectric ceramic actuators bonded to the plate surface and wired to produce pure bending. The error sensors are either microphones in the radiated far field or shaped PVDF sensors attached to one side of the

plate. The shaped PVDF sensors are rectangular strips positioned on the plate as discussed in Section 3.3, so as to observe only the odd-odd modes (the efficient modal radiators at low frequencies). The control arrangement is the multichannel feedforward implementation of the Filtered X algorithm discussed previously. The reference signal is taken from the noise input signal generator and is filtered as outlined in Eq. (17) before it is used in the LMS update equation, as described in Section 4.1.

Figure 13 presents results at 349 Hz, which is near the (3, 1) resonant frequency of the plate. The dotted

Figure 13 Active structural acoustical control performance for the system of Fig. 12: —, uncontrolled; - - -, controlled with PVDF structural error sensors; and . . . controlled with far-field error microphones; $f = 349$ Hz.²²

line for a case where three piezoelectric ceramic actuators are used in conjunction with three error microphones in the radiated far field, and it is apparent that global attenuations of approximately 25 dB are achieved. The dashed line is a similar case except that now two piezoceramic actuators are used in conjunction with two PVDF strips arranged in the x and y direction on the plate, as outlined in Section 3.3. The results again demonstrate good global control of approximately 20 dB in the radiated sound pressure levels. These results and others discussed in Ref. 3 demonstrate the potential of using ASAC to reduce radiated sound. For the ASAC technique there are two main mechanisms of control.¹⁶ *Modal suppression* corresponds to a direct reduction of the dominantly radiated modes or a fall in the plate wavenumber spectrum. *Modal restructuring* corresponds to the residual plate response having a lower overall radiation efficiency while its total magnitude of response is reduced only slightly or may even increase. This second case corresponds to attenuation of only supersonic components of the plate wavenumber spectrum while subsonic, nonradiating components are left unaffected. Thus the ASAC technique takes maximum advantage of the natural structural-acoustical coupling behavior to reduce the dimensionality of the controller. The technique has been successfully applied to the control of interior noise in aircraft and the reduction of transformer radiated noise as discussed in Refs. 3 and 4.

Active structural acoustical control systems have been successfully applied to propeller aircraft. Ultra Electronics has developed and marketed a system (called ATVA by Ultra) consisting of an array of electrodynamic actuators attached to the aircraft fuselage.³⁶ The actuators are used in conjunction with a feedforward controller to minimize the sum of the squares of the amplitudes of the pressure signals from an array of microphones located in the aircraft trim.³⁶ Reference signals were generated from the propeller shaft piper signals. When installed in a De Havilland Dash 8 aircraft, the ASAC system gives global reductions of the cabin sound field for the first four propeller tones. Measured attenuations range from around 10 dB at the propeller fundamental tone to 3 dB at the third harmonic.

From a system point of view, when multiple integrated actuators and sensors such as piezoelectric devices are used in conjunction with a non-model-based, adaptive controller, the application (such as ASAC discussed above) can be seen to be closely related to the field of *smart, adaptive* or *intelligent* structures (see Ref. 37 for a review of this field). Developments in the field of smart structures are likely to be used in advanced active vibration control and ASAC because of the inherent compactness, light weight, and adaptability of this class of systems.

CHAPTER 65

MICROELECTROMECHANICAL SYSTEMS (MEMS) SENSORS FOR NOISE AND VIBRATION APPLICATIONS

James J. Allen

MEMS Devices and Reliability Physics
Sandia National Laboratories
Albuquerque, New Mexico

1 INTRODUCTION

The use of microelectromechanical systems (MEMS) enables the fabrication of very small devices of overall size up to 1 to 2 mm and feature size as small as a micron. This capability enables sensors to be constructed with multiple axes, types, or arrays of sensors in the same package that enhance the ranges of applications for the sensors. However, issues of scale (size) impact the performance of a MEMS device that may necessitate the on-chip integration of microelectronics with the MEMS device, or special consideration to the method of signal transduction. MEMS are becoming more frequently used in noise and vibration problems and as miniature physical sensors for such applications as accelerometers, gyroscopes, pressure sensors, and microphones.

2 MICROELECTROMECHANICAL SYSTEM FABRICATION METHODS

2.1 Fabrication Processes

Microelectromechanical system fabrication has its roots in the microelectronics infrastructure. These fabrication techniques frequently involve a sequence of deposition, patterning, and etching to form a piece of material of a particular shape. This type of fabrication sequence is typically repeated a number of times in a microelectronic or MEMS fabrication technology. Figure 1 is a schematic illustration of this sequence.

The workhorse technique for defining the pattern for a material layer is lithography (either contact or optical). The lithography process uses a mask that contains an optically opaque pattern that is to be transferred to the material, and a thin photosensitive material (photoresist) that is applied on top of the material to be patterned (Fig. 1*b*). Contact lithography brings the mask into close proximity or contact with the photoresist and illuminated with a source to which the photoresist is sensitive. The illumination causes a chemical change in the photoresist that allows the photoresist to be developed and the pattern defined in the photoresist layer (Fig. 1*c*). For contact lithography the features on the mask are the same size as the features to be patterned in the photoresist. Optical lithography can pattern finer features through the use of an optical system allowing the patterns on the mask to be reduced in size and imaged on the photoresist.

Optical lithography is the method used in most high-resolution applications.

The underlying material can be etched using the patterned photoresist layer as a shield or mask to define the pattern in the material (Fig. 1*d*). There are a variety of etching processes that can etch the material isotropically or anisotropically depending on the material to be etched and etching process (wet chemical etch, plasma etch) utilized. Figure 2 illustrates anisotropic and isotropic etching of silicon materials. All of the instances shown in Figure 2 utilize a mask that is used to define an opening for the etchant to be exposed to the underlying material. An anisotropic etch can be performed on single-crystal silicon material with a wet chemical etch of potassium hydroxide (KOH). KOH etches 100 times faster in the (100) crystal direction than the (111) crystal direction. Patterned silicon dioxide, which KOH minimally etches, can be used as an etch mask for these type of etches. Very directional etches can be achieved with techniques such as this. Alternatively, an anisotropic etch of a material (Fig. 2*c*) can be achieved with dry plasma etches, which etch straight through the mask opening with near vertical sidewalls. An example of an isotropic etch is shown in Fig. 2*b*, which illustrates hydrofluoric (HF) acid isotropic etching of silicon dioxide through a masked opening.

These few paragraphs provide a brief flavor of the type of fabrication techniques involved in MEMS fabrication. The chemistry involved in the etching as well as the design and operation of the equipment of various fabrication steps are quite complex. More detailed information may be found in Refs. 1 and 2.

2.2 Microelectromechanical System Fabrication Technologies

There are three dominant MEMS fabrication technologies (Fig. 3) that have been developed during the past three decades. A fabrication technology is a combination of a set of underlying deposition, patterning, and etching processes that are combined to form a technology capable of fabricating MEMS devices.

- Bulk micromachining
- Sacrificial surface micromachining
- LIGA (lithography, Galvanofarming, abforming)

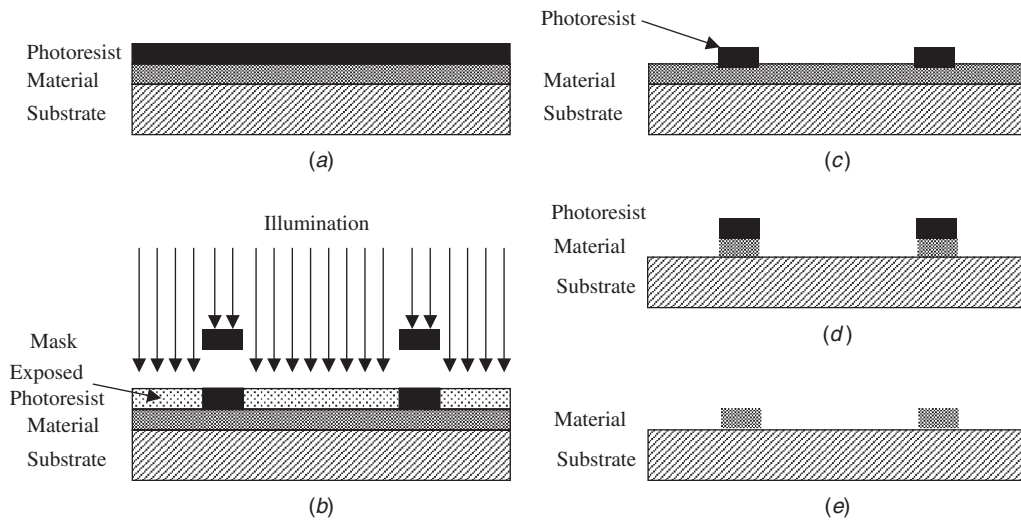

Figure 1 Pattern and Etch of a material deposited on a substrate. (a) Deposit a layer of material on a substrate and apply a thin layer photoresist. (b) Expose photoresist with a mask to define the pattern. (c) Develop and remove the exposed photoresist. (d) Etch material using the photoresist as a mask. (e) Strip photoresist.

Figure 2 Anisotropic and isotropic etches of silicon-based materials. (a) Anisotropic etch of single-crystal silicon. (b) Isotropic HF wet etch of silicon dioxide layer. (c) Anisotropic plasma etch of a silicon layer.

Each of these technologies is philosophically different in approach, but they each employ lithography to pattern the material with micron-size critical dimensions. Lithography is a technique that has been highly refined by the microelectronics industry to define micron and submicron features. Bulk micromachining and sacrificial surface micromachining are

most frequently silicon based and are generally very synergistic to the microelectronics industry since they tend to use the same materials and tool set.

Bulk micromachining utilizes wet³ or dry plasma etch⁴ processes to produce an isotropic or anisotropic etch profile in a material. Bulk micromachining can create large MEMS structures (10s of microns to a millimetre thick), which can be used for applications such as inertial sensing or fluid flow channels. Diaphragms useful in pressure sensors can be made by selective doping of the material, which affects the etch rate and selectivity. Commercial devices using bulk micromachining have been available since the 1970s. These applications include pressure sensors, inertial sensors, and ink-jet nozzles.

The concept of sacrificial surface micromachining (SSM) originated as far back as 1956,⁵ but the first demonstration of an SSM fabrication technology⁶ suitable for MEMS devices was accomplished in 1983. The fabrication processes used in SSM is a direct outgrowth of the microelectronic industry. This synergy provides a path toward the integration of electronics with MEMS structures that enable control and sensing functions in MEMS devices. SSM utilizes alternating layers of a structural material and a sacrificial material. A widely used material set for SSM is polycrystalline silicon and silicon dioxide for the structural and sacrificial material, respectively. SSM technologies can include as many as five layers of structural and sacrificial material that can be interconnected. SSM technology is generally limited to individual film thicknesses of 2 to 6 μm with an overall device thickness of <15 μm . Since the multiple layers can be connected during fabrication, the resulting devices are assembled as they are fabricated, thus relieving a very difficult task that gives

Figure 3 Dominant MEMS fabrication technologies. (Courtesy Sandia National Laboratories.)

SSM technology a large advantage for applications involving large arrays of devices. SMM technology has had several commercial successes in the last decade, which include optical mirror arrays⁷ and inertial sensors.⁸ Both of these applications include integrated microelectronics for sensing and control functions.

The LIGA technology was demonstrated in the 1986.⁹ This technology can fabricate devices with small critical dimension and high aspect ratio (i.e., thickness/width) with electroplated metallic materials. The metallic LIGA parts can be used directly or as a die for an injection molding process to produce plastic parts. This gives this technology the advantage in applications requiring a broader set of materials. LIGA technology has been used to fabricate piece parts such as springs, gears, and fluidic channels. Many applications require the LIGA piece parts to be assembled to perform their function. However, assembly of devices at the microscale is quite challenging, due to the large surface forces that exist at that scale.

Sacrificial surface micromachining and bulk micromachining are the MEMS fabrication technologies most relevant to production of noise and vibration sensors. However, each of these fabrication technologies has advantages and disadvantages relevant to the production of noise and vibration sensors as shown in Table 1.

2.3 Integration of MEMS and Electronics (IMEMS)

Of the three MEMS fabrication technologies previously discussed, surface micromachining is the most amenable to integration with electronics to form an

Table 1 Comparison of Bulk Micromachining and Sacrificial Surface Micromachining

Bulk Micromachining	Sacrificial Surface Micromachining
Advantages	
Large seismic masses (high aspect ratio etches)	{ Volume production Low cost in volume production On-chip integration of electronics Complex electrode structures and interconnection
Lower cost fabrication facilities	
Disadvantages	
Package level integration of electronics	Thin layers (limited seismic mass)
Device complexity limited	High-cost fabrication facilities

IMEMS process. There are several challenges to the development of an IMEMS process:

- **Large Vertical Topologies** Microelectronic fabrication requires planar substrates due to the use of precision photolithographic processes. Surface micromachine topologies can exceed 10 μm due to the thickness of the various layers.
- **High-Temperature Anneals** Mitigation of the residual stress of the surface micromachine structural layers can require extended period time at high temperature (such as several hours

at 1100°C for polysilicon). This would have adverse effects due to the thermal budget of microelectronics that is limited due to dopant diffusion and metallization.

There are three strategies for the development of an IMEMS process.¹⁰

- *Microelectronics First* This approach overcomes the planarity restraint imposed by the photolithographic processes by building the microelectronics before the nonplanar micromechanical devices. The need for extended high-temperature anneals is mitigated by the selection of low-temperature anneal MEMS materials (e.g., aluminum, amorphous diamond) and/or selection of the high-temperature microelectronic metallization (e.g., tungsten instead of aluminum), which make the MEMS and microelectronic processing compatible. An example of this approach includes an all-tungsten complementary metal–oxide–semiconductors (CMOS) process that was developed by researchers at Berkeley Sensor and Actuator Center.¹¹
- *Interleave the Microelectronics and MEMS Fabrication* This approach may be the most economical for large-scale manufacturing since it optimizes and combines the manufacturing processes for MEMS and microelectronics. However, this requires extensive changes to the overall manufacturing flow to accommodate the changes in the microelectronic device or the MEMS device. Analog Devices has developed and marketed an accelerometer and gyroscope that illustrates the viability and commercial potential of the interleaving integration approach.¹²
- *MEMS Fabrication First* This approach fabricates, anneals, and planarizes the micromechanical device area before the microelectronic devices are fabricated, which eliminates the topology and thermal processing constraints. The MEMS devices are built in a trench that is then refilled with oxide, planarized, and sealed to form the starting wafer for the CMOS processing. Figure 4 is an example of a three-axis accelerometer fabricated in the MEMS fabrication first approach.

3 SCALING ISSUES

Microelectromechanical Systems technology has allowed the design and engineering of systems that can be 1000 times smaller than previously achieved. At these large changes in scale, our macroworld intuition of the relevant physics may be erroneous. Our engineering intuition at the microscale may be change due to:

- Physical phenomena scale at different rates that changes their relative importance

Figure 4 Multiaxis accelerometer fabricated in the MEMS first IMEMS process. (Courtesy Sandia National Laboratories.)

- Entering different physics regimes at a particular scale

To evaluate the impact of scaling, we will consider an isomorphic scaling of the system geometry (i.e., all dimensions scaled equally). A dimension of length X_0 can be scaled to a smaller dimension X_s by a scale factor, S [Eq. (1)]. Since we are studying the effect of scale reduction, $0 < S \leq 1$. The scaling of area and volume may be considered in a similar manner:

$$X_s = SX_0 \quad (1)$$

Two fundamental parameters describing a mechanical system are the mass and stiffness. Since the mass is simply the product of volume and density, the mass scales as S^3 (i.e., the mass is decreasing with the cube of the scale factor):

$$M_s = \rho S^3 V_0 = S^3 M_0 \quad (2)$$

The stiffness describes the ability of a mechanical system to resist applied forces. Stiffness, K , is the ratio of the force applied to the resulting deflection. Equation (3) shows the proportionality relationship between beam bending stiffness and Young's modulus of the material, beam width, and thickness. Isomorphic geometric scaling shows that the bending stiffness, K_{bending} , reduces proportionally with the size scale:

$$K_{\text{bending}} \propto \frac{Ewt^3}{L^3} \propto S \quad (3)$$

Since the mass and stiffness of a system are changing at significantly different rates, the system dynamics will be affected. For example, the natural frequency of a one-degree-of-freedom mechanical system is defined as the square root of the stiffness divided by the mass [Eq. (4)]. The scaling parameters

for mass and stiffness that have been developed above have been inserted to show that as a system reduces in scale, S the natural frequency scales, by $1/S$. This means the natural frequency increases for system scale reductions. The effect is due to the stiffness decreasing more slowly than the mass for a reduction in size:

$$f_n = \frac{1}{2\pi} \sqrt{\frac{K}{M}} \propto \sqrt{\frac{K}{M}} \propto \sqrt{\frac{S}{S^3}} \propto \frac{1}{S} \quad (4)$$

It has been noted that MEMS-scale devices are more rugged in mechanical shock and vibration environments than their macroworld counterparts. MEMS inertial sensors have been shown to survive shock environments of tens of thousands of g 's.¹³ However, the scaling of natural frequency also reduces the mechanical sensitivity of the device, which motivates the use of IMEMS technology to increase the electrical sensitivity and reduce parasitics, which degrade performance.

Ratios such as the area-to-volume ratio are significant in many engineering fields, especially fluid dynamics and heat transfer. The area-volume ratio scales as the inverse of S [Eq. (5)]. Therefore, as systems are reduced to the MEMS scale, the area-volume ratio increases; this implies that physical phenomena sensitive to the area-volume ratio will change from our heuristic macroworld expectations. For example, heat transfer at the microscale occurs very rapidly. This scaling of the area-volume ratio makes surface forces and surface tension significant at the microscale:

$$A_s/V_s = 1/S(A_o/V_o) \quad (5)$$

Brownian noise, also called *thermal noise* or *Johnson noise* for electrical systems, is a low-level noise present in both electrical and mechanical systems. This noise source becomes significant for MEMS devices due to small size.¹⁴ This thermal noise is present everywhere in our environment and is due to such things as the vibrations of atoms in the materials from which a device is made and the environment in which the device operates. Thermal noise is a function of temperature of these materials. The mechanisms that couple these thermal vibrations to the mechanical or electrical device of interest are the energy dissipation mechanisms (i.e., damping for mechanical devices, resistance for electrical devices). As a device is reduced in size, these thermal noises or vibrations become significant for MEMS-scale sensors. The total noise equivalent acceleration (TNEA) due to thermal noise of an inertial sensor is given by Eq. (6). TNEA is the minimum acceleration that can be sensed:

$$\text{TNEA} = \sqrt{\frac{4K_B T \omega_n}{QM}} \quad (\text{m/s}^2 \sqrt{\text{Hz}}) \quad (6)$$

where T = temperature (Kelvin)

K_B = Boltzmann constant (1.38×10^{-23} J/K)

ω_n = natural frequency

Q = quality factor

M = mass

4 SIGNAL TRANSDUCTION METHODS

4.1 Piezoresistance

The piezoresistive effect was first discovered by Lord Kelvin in 1856, which lead to the use of metal and foil strain gauges that have been used for many years. The piezoresistive effect is a change in electrical resistance of a material due to applied mechanical strain. The discovery of the piezoresistive effect in silicon¹⁵ in 1954 had significant impact in the development of MEMS for the following reasons.

- Integration with MEMS devices and microelectronics is possible due to material compatibility.
- Integration of the piezoresistive material and the MEMS device allow good transmission of strain without hysteresis or creep.
- The piezoresistive effect in silicon is over an order of magnitude greater than metals.
- MEMS fabrication processes allow good matching of resistors utilized in the Wheatstone bridge sensing circuits.

As a result of these advantages, piezoresistive sensing has been used as a transduction method for MEMS pressure and inertial sensors for many years. Piezoresistance transduction does not require on-chip electronics, which allows for lower cost, however, piezoresistive sensing may be limited by the Johnson noise of the resistors.

4.2 Capacitance Sensing

Electrostatic capacitance sensing is a frequently used transduction method for MEMS devices since capacitors with small electrode spacing may be readily made and integrated into the device. Matched capacitors can be readily made with MEMS fabrication technology, which enables differential sensing. Differential capacitors can be fabricated in such a manner that the two capacitors have the near equal capacitance in the unperturbed position, and change by equal and opposite amounts as the structure is deflected. The differential capacitor structure enables differential sensing that can cancel many adverse or common-mode effects to first order. Changing two capacitors by the same amount is a common-mode effect to which a differential capacitor structure does not respond.

The size of the capacitors utilized in MEMS devices are small, generally a fraction of a picofarad. The variation of the nominal capacitance that is to be sensed to provide the dynamic signal of interest is in the femtofarad range or less. There are also undesirable stray capacitances called *parasitic capacitances* that can interfere with capacitance sensing electronics. The parasitic capacitances will increase the overall electrical time constant of the device and limit the frequency at which it can be electrically charged and discharged, which will have an adverse affect on the sensor interface. Therefore, capacitive sensing typically required an integrated MEMS and electronics process where the electronics is on the same substrate

adjacent to the MEMS device. This will minimize the parasitic capacitances and increase the device sensitivity. Capacitance transduction is frequently used for high-resolution MEMS sensing.

5 MEMS PHYSICAL SENSORS

Since 1980 the MEMS field has made dramatic progress. MEMS fabrication processes have matured, enabling increased commercialization of MEMS applications that include optical mirror arrays for displays, inertial sensors, and DNA (deoxyribonucleic acid) analysis systems. This section will discuss the implementation of MEMS physical sensors such as accelerometers, gyroscope, pressure, and noise sensors. The use of MEMS noise and vibration sensors can provide significant advantages that include:

- Low-cost large-volume production
- Multiple devices within the same package
- Improved time response of the system
- Sensor arrays that may be used for directionality or intensity measurements

5.1 Microelectromechanical Systems Accelerometers

Microelectromechanical Systems accelerometers have found applications ranging from measurement and control to inertial navigation. MEMS implementations of accelerometers have found a large commercial market in automotive airbag deployment systems.⁸ The basic components of an accelerometer consist of the inertial mass, suspension, and sensing element (Fig. 5). The inertial mass suspension will deflect under acceleration. The sensing element will measure the relative deflection, Z , of the inertial mass and accelerometer case. The transduction can be accomplished by a number of means, but the most common for MEMS devices are piezoresistive and capacitance:

$$M\ddot{Z} + C\dot{Z} + KZ = M\ddot{y} \quad (7)$$

The mechanical sensitivity of an accelerometer, S_M , is the relationship between the relative deflection

Figure 5 Schematic illustration of an accelerometer.

of the inertial mass and case, Z , and the input acceleration, \ddot{Y} . Since the operating range of the accelerometer is at low frequency, where $\omega \approx 0$, an acceleration input to the system may be approximated by a constant acceleration balanced by the suspension [Eq. (8)]. Hence the mechanical sensitivity, S_M , of an accelerometer is shown in Eq. (9). Figure 4 is an example of a capacitance-sensed accelerometer fabricated in the MEMS first IMEMS process:

$$KZ = M\ddot{Y} \quad (8)$$

$$S_M = \frac{M}{K} = \frac{1}{\omega_n^2} \quad (9)$$

5.2 Microelectromechanical Systems Gyroscopes

A gyroscope is an instrument for measuring angular rate (i.e., the rate an object turns). A vibratory gyroscope has been the principal approach for implementation in MEMS technology. Vibratory gyroscopes are based on *Coriolis acceleration*, which is acceleration produced due to the changing direction in space of the velocity of the body relative to the moving system.

For example, consider a mass M moving along a radial path on a platform rotating with angular velocity Ω , shown in Fig. 6. The tangential velocity, V_t , increases as the mass moves further from the center of rotation [Eq. (10)]. For the mass to move outward (i.e., r increases) on a radii relative to the platform the tangential velocity will need to increase:

$$V_t = \Omega r \quad (10)$$

The rate of increase of the tangential speed caused by the radial velocity, V_r , in a rotating system is *Coriolis acceleration*, a_{Coriolis} . An additional component of Coriolis acceleration arises from the changing direction of the radial velocity, which yields the following expression for Coriolis acceleration:

$$A_{\text{coriolis}} = 2\Omega \times V_r \quad (11)$$

Figure 6 Illustration of Coriolis acceleration.

Figure 7 Tuning Fork Gyro (TFG) Schematic.

A vibratory gyroscope is comprised of a resonator that will oscillate a body along one axis and measure the orthogonal movement or force on the body due to Coriolis acceleration. The detection of Coriolis acceleration is the basis of a vibratory gyroscope.

Figure 7 is a schematic of a type of vibratory gyroscope known as a tuning fork gyroscope (TFG) that is being driven along the x axis, the rotation rate to be measured, Ω , is along the z axis, and the Coriolis acceleration response is sensed along the y axis. Equations (12) and (13) are the equations of motion (force balance) for the body in the drive and sense axes, respectively. These are a system of coupled second-order equations that are coupled via the Coriolis acceleration terms. The physical mechanism for a vibratory gyroscope is the transfer of energy from one resonator axis to another via the Coriolis acceleration coupling. The suspension for this device can have a unique natural frequency, ω_x , ω_y , and a unique damping ratio for ζ_x , ζ_y each axis [Eq. (14)]. Frequently, ω_y is designed to be slightly less than ω_x , which will provide a modest mechanical gain without significant bandwidth or phase shift reductions.

The gyroscope will require the mass to be driven in the x axis a force, F_x , which is generated by electrostatics. The drive amplitude is very accurately controlled by an automatic gain control feedback loop since any variation will directly contribute to sensor error. Because the oscillatory drive portion of the gyroscope [Eq. (12)] is fixed to a high degree of accuracy by the gain control loop, Eq. (13) governs the dynamics of the gyroscope response. Since the Coriolis term input to Eq. (13) is a *modulated* signal, the gyroscope output will need to be *demodulated* to extract the rotation rate signal.

Erroneous signals (*quadrature error*), which contaminate the Coriolis signal, can be generated by dynamic force imbalances (stiffness, mass, electrostatic) in the vibrating structure. Quadrature errors can be minimized by error cancellation or synchronous detection methods to extract the Coriolis signal:

$$\ddot{x} + 2\zeta_x\omega_x\dot{x} + \omega_x^2x = \frac{1}{M}F_x - 2\Omega\dot{y} \quad (12)$$

$$\ddot{y} + 2\zeta_y\omega_y\dot{y} + \omega_y^2y = 2\Omega\dot{x} \quad (13)$$

$$\omega_y = \sqrt{\frac{K_y}{M}}\omega_x = \sqrt{\frac{K_x}{M}} \quad (14)$$

The first silicon integrated micromachined vibratory gyroscope was described by O'Connor and Shupe in 1981.¹⁶ In the ensuing years, development of a MEMS gyroscope was spurred by the lure of a low-cost, mass-producible instrument. The configuration that has been employed both for macroscale and MEMS vibratory gyroscopes is the *tuning fork gyro* (TFG) (Fig. 7). The TFG consists of two plates that are driven in an antiphase manner (i.e., both plates move outward and inward relative to the center axis). The rotational field will cause the plates to move perpendicular to the substrate in opposite directions. This configuration enables differential sensing that will allow common-mode signals such as external accelerations to be rejected. The use of two masses vibrating in antiphase also causes momenta to cancel locally and make the gyroscope less sensitive to mounting. The two masses may have coupled or separate suspensions. Two MEMS TFGs have been successfully developed for commercial applications by Draper

Laboratories^{17,18} and Analog Device.¹⁹ Both of these gyroscopes have achieved resolutions in the low tens of degrees per hour range. The applications for a gyroscope such as this include tactical grade navigation, platform stabilization, automobile skid control, and stabilization.

The development of a MEMS spinning mass gyroscope was initially inhibited due to the lack of low friction bearings and the significant stiction and adhesion forces at the microscale. However, promising research on the development of an electrostatic levitated spinning mass MEMS gyroscope is proceeding.^{20,21} This is an ambitious approach due to the necessity of closed-loop control to stabilize the levitation, in addition to driving the spinning mass and sensing its deflections due to precession. This approach is currently in the research stages with no MEMS spinning mass gyroscope commercial products available.

5.3. Microelectromechanical Systems Pressure and Noise Sensors

Most pressure sensors for greater than atmospheric pressure utilize a deformable diaphragm between a reference cavity containing a known pressure or a vented cavity, for absolute or relative pressure measurements, respectively. The deflection of the diaphragm is the measure of pressure that can be sensed by capacitive or piezoresistive means. The pressure sensor may measure absolute pressure, which has a vacuum or a reference pressure on one side of the diaphragm. Alternatively, a gauge pressure or differential pressure sensor would have one side of the diaphragm vented to atmosphere or to another pressure that would be a reference for the measurement.

Pressure sensors may be fabricated with bulk micromachining methods to form the cavity and diaphragm. The shape of bulk micromachined cavities are restricted by crystal orientation if anisotropic etching is used. The shape of surface micromachined pressure sensors are not restricted since they are photolithographically defined. Figure 8 shows a surface micromachined pressure sensor²² which has a 2- μm -thick diaphragm, 200- μm diameter that is piezoresistively transduced.

A microphone is a dynamic pressure sensor where frequency response and mechanical sensitivity are important. The acoustic resistance and squeeze film damping between the diaphragm and stationary cavity typically minimize the effectiveness of a MEMS pressure sensor as a microphone. The design of the pressure sensor is typically modified through the use of perforated stationary plates²³ and venting into a larger cavity to produce a microphone with a flat frequency response over a broad frequency range. Piezoresistive²⁴ and piezoelectric²⁵ MEMS microphones have been reported as well as MEMS hydrophones.²⁶

6 CONCLUDING REMARKS

The MEMS industry is thriving and growing rapidly largely due to the diversity of applications in which

Figure 8 Surface micromachined pressure sensor.²² (Courtesy Sandia National Laboratories.)

MEMS devices provide a solution. For example, today's automobiles have a number of MEMS sensors, which include accelerometers, gyroscopes, pressure sensors, wheel speed sensors, and oil condition sensors.²⁷ MEMS devices can produce unique capabilities for noise and vibration applications due to their small size, which will minimize the mass loading effect during measurement and the use of multiple sensors or arrays in one package that will enable unique measurement and diagnostic features.

CHAPTER 66

DESIGN OF LOW-NOISE MACHINERY

Michael Bockhoff

Ingénierie Bruit et Vibrations

Centre Technique des Industries Mécaniques (CETIM)

Senlis, France

1 INTRODUCTION

This chapter presents a systematic approach aimed at integrating noise control aspects into the design process of entirely new machines or of machines to be redesigned partially. The main task of a designer of machines is to find solutions and to set up means that ensure the principal functions expected of the new machine. Generally, the choices and technical possibilities are limited by a group of additional requirements relative to cost, user friendliness, pollution, noise, and the like, which are difficult to reconcile; in particular, the function of low noise emission is not always compatible with parameters such as low cost, lightweight, and compactness.

Low-noise design is an important feature in many types of machinery, such as industrial machinery and equipment for the protection of operators, transportation systems, machinery used outdoors to reduce annoyance in residential neighborhoods, mechanical and ventilation equipment in buildings, household appliances, and car equipment to improve the comfort of passengers.

To meet the requirements of low-noise design in such a broad range of applications, the designer needs a general approach to machinery noise problems. Therefore, methodology for low-noise design needs to cover acoustical analysis and evaluation of the whole machine, its components, and underlying mechanical principles. It also must include rules and recommendations for noise reduction applicable at the different stages of the design process. Designers of machinery must be able to evaluate different possible design solutions with respect to noise criteria and to select the most appropriate one.

2 DESIGN PROCESS AND NOISE CONTROL

2.1 Background

During the last 50 years general design methodologies have been set up, especially in Germany, and improved continuously.^{1–4} A review is presented in Ref. 5. More recent works include also computer-assisted approaches.^{6,7} Noise control of machinery is presented in most textbooks dealing with technical acoustics and vibrations.^{8–11} The methodical link between both noise control and design has been developed more recently, mainly in Europe.^{12–18} Some of these authors (together with the author of this chapter) have participated—in the frame of the International Organization for Standardization (ISO)—in an elaboration of a technical report on this matter.¹⁹ Some

dedicated software has also become available: The EQUIP+ system was initially developed as prototype software within the scope of a European Brite-Euram project EQUIP.²⁰ The current version is the result of further development by TNO TPD, Netherlands. It consists of an information system and a noise path modeler for visualizing and quantifying the noise situation of machinery. The PRONS system (Product Noise Synthesiser) has similar features; issued from another European research project,²¹ it is marketed by Head Acoustics GmbH, Germany.

Most of the acoustical concepts and methods used in this chapter are mentioned without any further theoretical development because they are already presented in detail in other chapters: for example, measurement techniques in Part V (especially Chapters 43 to 50), modeling techniques in Chapters 7, 8, and 17, and methods for noise and vibration control in Parts VI and VII.

2.2 Concept of Low-Noise Design

Modern design procedures, used today by mechanical engineers, proceed in well-defined steps. Starting from a level of low knowledge about the future object, the following stages integrate successively the needed information and become more and more specific.

The concept of low-noise design of machinery is based on the same approach, but in addition it integrates at each step of the process the appropriate noise control aspects. Figure 1 shows a complete four-step scheme (according to Ref. 19) where the left column represents the general design process and the right column the needed inputs of acoustical knowledge at each step.

Clarification of Task At this stage the functional, economical, and safety requirements for the future product have to be listed, including noise specifications. Depending on the specific design task, these specifications will make reference to

- Legislation
- State of the art
- Requests from clients
- Products of competitors
- Sales arguments, and so forth

Conceptual Design Here potential solution principles have to be compared and the most appropriate ones selected. Knowledge on the final product is still limited; nevertheless, first statements on noise

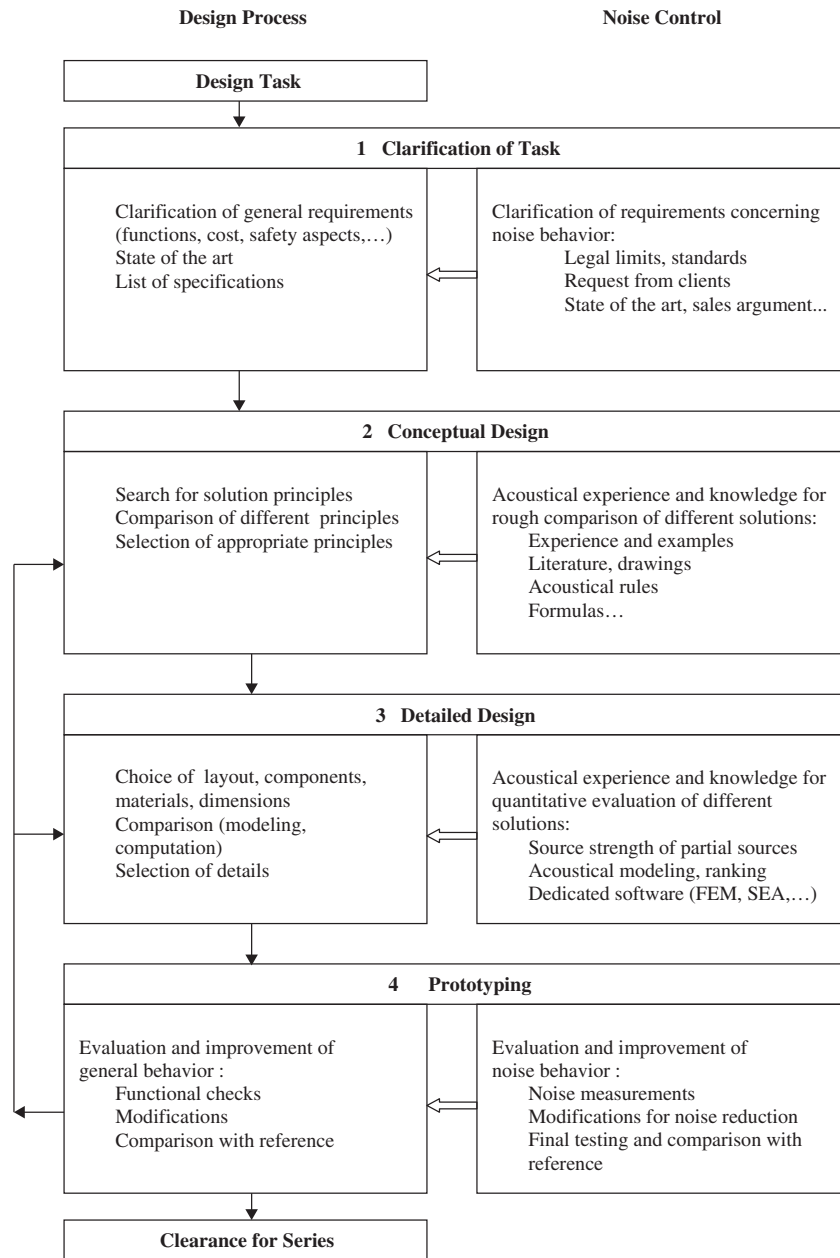

Figure 1 Stages of the design procedure.

behavior can be made by comparison to existing products, literature, former experience, and the like.

Detailed Design Next, the general layout of the machine, basic materials, and individual components are defined. At this point it becomes easier to make reasonable estimates for the expected noise emission and to compare different design options.

Prototyping Once the first prototype is built, noise and vibration measurements allow checking the overall behavior. In general, the results will not yet comply with the specifications and design improvements are needed. At this stage it becomes necessary to quantify major noise sources and sound paths. A priority list of noise control measures has to be set up that can potentially be implemented to reduce the noise emission.

3 CLARIFICATION OF TASK

To set up noise specifications for the future product, it is necessary to define first the noise emission quantities and corresponding measurement procedures (standardized or not) to be used and noise emission values serving as design targets.

Typical quantities are, for example:

- A-weighted sound power level L_{WA} according to ISO 3744 series
- A-weighted emission sound pressure level L_{pA} at the workstation according to ISO 11200 series
- Sound pressure spectra in one-third-octave bands at selected measurement points
- Psychoacoustic parameters such as loudness, roughness, sharpness, and the like

The targets can be defined, for example, with the help of:

- Legal limits existing for specific products
- Limits required by clients
- State of the art
- Company-specific requirements, and the like

4 CONCEPTUAL DESIGN

In general the determination of absolute noise values (e.g., by using rough empirical formulas) is difficult and only a ranking of solution principles can be achieved. Sometimes the differences between principles can be estimated from acoustical rules. Since in any design solution each functional system is linked to a physical operation principle, both have to be considered for the choice of a design concept.

Basic Rule The mode of operation with the lowest speed and changes in speed (acceleration) will generally provide the best acoustical solution. That applies to the motion of solid parts as well as to liquid and airflow.

It can be concluded that in the following ranking of dynamic principles an increasing improvement should be expected with the later solutions:

- Shock or impact
- Oscillating motion (back and fourth)
- Continuous translation or rotation

5 DETAILED DESIGN

5.1 Acoustical Modeling

To prepare a quantitative estimate of the noise emission of the future product, it is useful to set up an acoustical model, which distinguishes between the different types of noise and visualizes its global noise behavior. The basic model, which illustrates the principle, is shown in Fig. 2.

Here it is assumed that the noise generation mechanism (NGM) is a simple force $F(\omega)$. The machine is

Figure 2 Basic acoustical model of a machine. $F(\omega)$, excitation force; $v_0(\omega)$, input velocity; $v(\omega)$, surface-averaged mean velocity; $A_0(\omega) = v_0(\omega)/F(\omega)$, input mobility; $T(\omega) = v(\omega)/v_0(\omega)$, transfer function; $\sigma(\omega)$, radiation efficiency; S , machine surface; $W(\omega)$, radiated sound power; $\omega = 2\pi f$, angular frequency.

characterized by an input mobility $A_0(\omega)$ and a transfer function $T(\omega)$; its response is given by the input velocity $v_0(\omega)$ and by the resulting vibration velocity, averaged over the surface S , $v(\omega)$. The radiation behavior is controlled by the radiation factor $\sigma(\omega)$, which, together with the surface S , determines $W(\omega)$. It is then possible to express the radiated sound power $W(\omega)$ as a function of $F(\omega)$ by the following equation:

$$W(\omega) = \rho c \sigma(\omega) S T^2(\omega) A_0^2(\omega) F^2(\omega) \quad (1)$$

or

$$W(\omega) = \rho c(\omega) S A_T^2(\omega) F^2(\omega)$$

with

$$A_T(\omega) = T(\omega) A_0(\omega) \quad (\text{transfer mobility})$$

In logarithmic form this becomes

$$L_W(\omega) = L_F(\omega) + L_{SA_T^2}(\omega) + L_\sigma(\omega) \quad (1a)$$

The mechanical excitation of a structure can be considered to be *force controlled* when the load due to the structure has no significant influence on the force. This is the case when the input mobility of the structure is negligible compared with the internal mobility of the source component. (Examples: heavy, massive steel structures such as combustion engines, gear boxes, etc., excited by small components.)

The other limiting case is the *vibration controlled* excitation, which is observed when the input mobility of the structure is much higher than the internal mobility of the source. (Examples: lightweight structures such as platelike covers, panels of enclosures, etc., excited by heavy machinery parts.) In that case the radiated sound power can be calculated by a slightly modified equation:

$$W(\omega) = \rho c \sigma(\omega) S T^2(\omega) v_0^2(\omega) \quad (2)$$

The representation in Eq. (1a) of the sound power level $L_W(\omega)$ as a sum of three terms that reflect different physical mechanisms can be very helpful for understanding the acoustical chain and the possibilities of noise reduction. Figure 3 shows a graphic

Figure 3 Graphic illustration of Eq. (1a). The resulting sound power level is the sum of partial levels representing contributions of generation, transmission, and radiation.

illustration of Eq. (1a): The “machine” structure is a simply supported steel plate and the excitation is given by repeated (rectangular) shocks. The plotted spectra have been strongly simplified. $L_F(\omega)$, for example, which in reality is a line spectrum, has been replaced by its envelope, approximated by two straight lines. To show how this representation can reveal typical (antagonistic) trends in noise reduction, the curves are plotted for two values of plate thickness e but unchanged excitation. It is seen that in some frequency bands increased thickness reduces noise radiation, but in others (due to a higher radiation coefficient) noise radiation is even stronger.

In practice, calculations may be much more complex than suggested by Eq. (1) or (2) because real excitations are generally more complex (not simple, pointlike forces or vibrations, oriented in a direction perpendicular to the surface but combinations of forces and torque or situations where both, force and vibration, have to be considered, etc.). Nevertheless, Eqs. (1) and (2) show at least the general trend and point out already the parameters on which noise control actions could be taken.

The first step for setting up an acoustical model is to divide the machine in active and passive components:

- Active components are characterized by the presence of one or more noise generation mechanisms (NGM) (such as impact, unbalance, pressure fluctuations, turbulence).
- Passive components do not generate noise; they only transmit noise to other machine parts or radiate it to the outside.

In the next step NGMs and active components, divided into structure-borne, liquid-borne, and airborne types, should be detailed and located. Then the transmission paths of all contributions have to be analyzed. Finally, the potential radiating surfaces have to be identified.

To avoid confusions, two domains have to be distinguished when describing the causal chain of noise generation: When acoustical mechanisms are analyzed, the causal chain is presented in terms of generation–transmission–radiation. When the physically involved machinery components are considered, the chain is presented in terms of source–path–surface. This representation is generally the more convenient for the designer. The graphic representations of these two domains are different. Figure 4 shows both for the example of a lawnmower.

The building of a visual model of the machine is an important step in the characterization of the noise situation, even if designers often would prefer to establish directly a more sophisticated calculation model. Therefore, the central module of the EQUIP+ software, mentioned in Section 2.1, is a *noise path modeler*. This software allows to set up rather quickly a component-based model by selecting noise relevant components, a receiver, and appropriate links. As an illustration, Fig. 5 presents the noise path model obtained for a diesel unit, which can be considered as a zoom-in on one of the main components (the “engine”) of the lawnmower model shown in Fig. 4. (Except lawnmowers are usually powered by gasoline engines and actual enclosures are generally very partial ones.)

Sometimes an even more detailed description of the machine may be needed. For example, if the radiation from the enclosure is dominant, it is necessary to distinguish between contributions from different walls and from openings. Generally, these improvements will be introduced only after a first ranking of contributions.

5.2 Ranking

To identify the dominant contributions to the overall noise, a ranking has to be made within each of the three steps of the chain (generation–transmission–radiation)

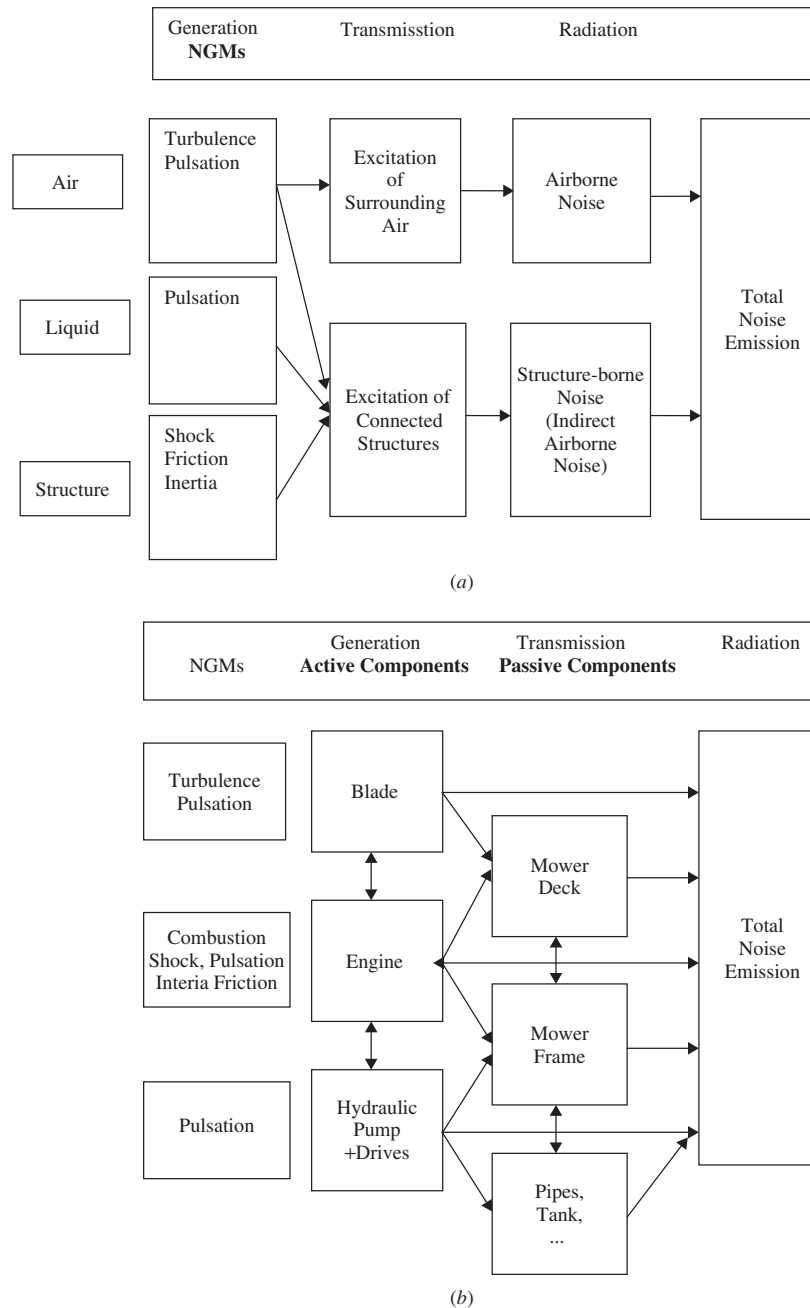

Figure 4 Acoustical models of a ride-on lawnmower. (a) NGM-based model and (b) component-based model.

and for each noise type (structure-borne, liquid-borne, and airborne). If no particular information from similar products or former design solutions is available, the ranking will remain rough and qualitative, and conclusions have to be confirmed later during the prototype stage. Improvements of the prediction need

detailed input data and computation tools such as finite element models (FEM), SEA, or analytical models.

5.3 Rules for Noise Control

Once the dominant sources with their transmission paths and radiation areas are identified, improved

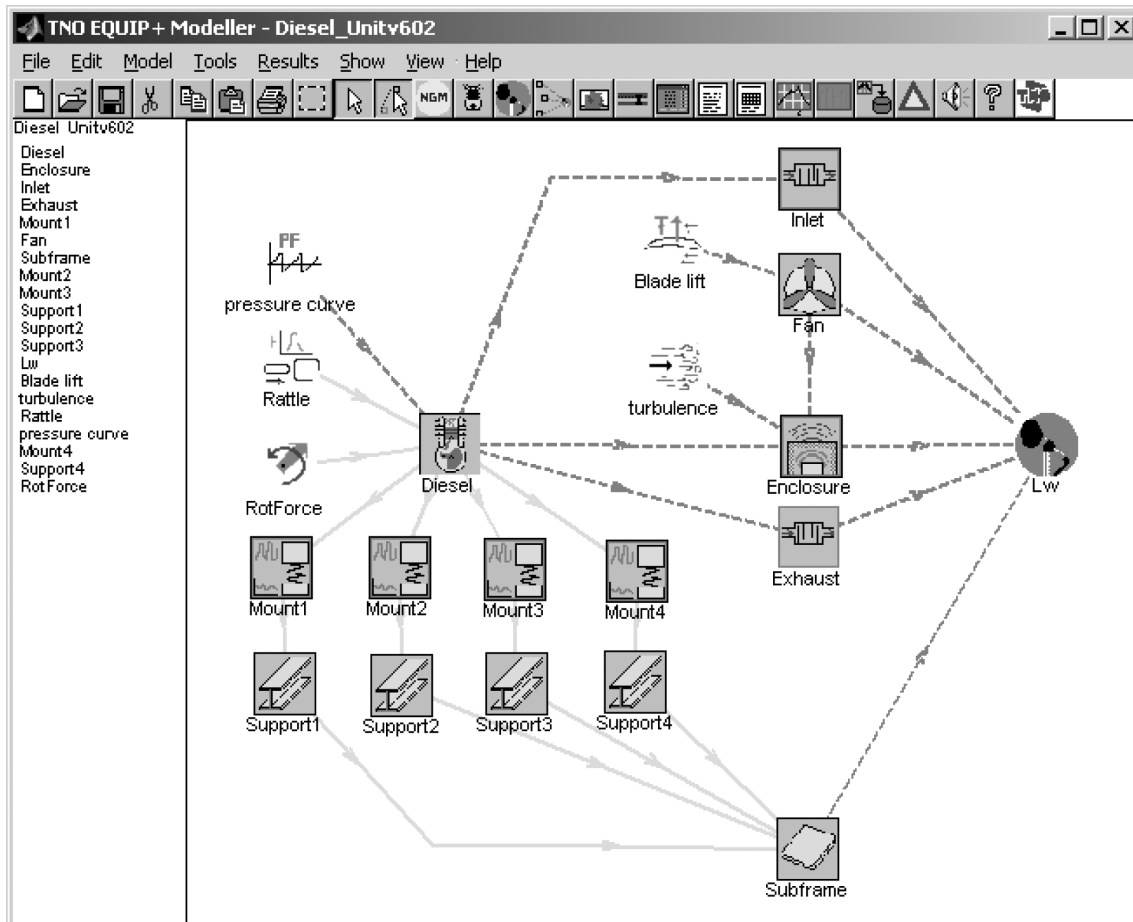

Figure 5 Noise path model of a diesel unit, built with EQUIP+ software. (Courtesy TNO Delft, The Netherlands.) Square icons, components; circular icons, noise generation mechanisms (NGMs). Full arrows, structure-borne noise paths; dotted arrows, airborne noise paths.

design solutions can be elaborated. It is recommended to consider, first, the active components and, second, the passive components (transmission paths and radiation). Among the sources, of course, the dominant contributions have to be controlled first. Tables 1 to 3 present general design rules for the control of generation, transmission, and radiation of noise.

6 PROTOTYPING

6.1 General

The purpose of actions undertaken in this stage is to obtain compliance with target values such as legal or contractual limits, company targets (product improvement), or the state of the art (comparison with competitors). The procedure is generally an iterative one with the following steps:

Measurements

- Overall check: When compliance with the design tasks is achieved, the acoustical part of

prototyping is finished, otherwise the procedure continues.

- Detailed measurements (research of predominant sources and transmission paths)

Evaluation

- Ranking of sources
- Planning of noise control measures (priority list)

Modification

- According to priority list

6.2 Measurements

6.2.1 Overall Check Target values are very often single numbers that can be measured rather easily according to standardized test codes or other simple procedures defined in advance (A-weighted sound power level L_{WA} , A-weighted emission sound pressure level L_{pA} at the workstation or at specific positions, etc.).

Table 1 Design Rules to Control Noise Generation

Noise Type	NGM	Generation
		Design Rules
Airborne	Turbulence	Avoid obstacles in the flow and flow over cavities (generation of pure tones) Smooth flow profile Minimize flow velocity (increase diameter of ducts) Reduce pressure drops along the flow For jets, improve outlet geometry (minimize velocity changes across the jet) For nozzles, replace single hole outlet by multiple holes of smaller diameter (shift of dominant noise to nonaudible frequencies) For fans, minimize tip speed and increase clearance between rotor and casing
	Pulsation	Avoid obstacles near rotating blades of fans, turbines, etc. (generation of tonal noise) Smooth pressure pulsation (i.e., lower amplitude of pulses, increase rise time of pulses)
	Shock	Slow down pressure–time variation when releasing pressurized gas In supersonic flows reduce flow velocity
Liquid borne	Turbulence, pulsation, shock	Same rules as for airborne noise
	Cavitation	Avoid that static pressure along the flow drops below vapor pressure Smooth flow profile of pumps and valves Keep suction line short Place pump outlet higher than inlet Use a flow resistance in the outlet (creates a counterpressure) Reduce flow speed
Structure borne	Impact	Reduce the mass of impacting body Increase the fixed mass Avoid loose parts and play
	Tooth meshing	Use helical gears Increase the number of teeth Improve tooth profile quality Use plastics for low load
	Rolling	Increase flexibility in the contact area Use precision roller bearings Reduce tolerances in housing Use proper lubrication Keep rolling surfaces smooth
	Inertia	Optimize steadiness of motion (no accelerated masses) Reduce inertia forces by proper balancing
	Friction	Reduce friction by appropriate choice of materials Reduce friction by lubrication
	Electromagnetic fields	Optimize shape of poles in electric motors Optimize number and position of slots in electric motors For transformers reduce magnetostriction by selection of proper core material

In practice, problems may nevertheless occur in the choice of the test site:

- When the machine cannot be mounted in an acoustical test room—This generally is the case with big machines or when auxiliary equipment is needed (driving unit, fluids, etc.).
- When the nominal operating conditions cannot be achieved easily (e.g., lack of material or insufficient power).

If noise measurements are to be made at arbitrary industrial locations, preliminary tests are necessary to qualify the test environment (background noise, reverberation). Commonly used procedures are based on

outdoor measurements (no reverberation), measurements during night (no background noise) or measurements at the customer's site (auxiliary equipment). If no particular (standardized) test code is prescribed, the choice of the measurement method and appropriate instrumentation have to take into account the nature of expected noise.

6.2.2 Detailed Measurements When the overall check has revealed unacceptable high noise levels, more detailed measurements are needed to understand the noise generation mechanisms and to define noise control measures. As shown in Fig. 6, the analysis should be focused on the basic elements used in the design stage, but in a different order of the steps.

Table 2 Design Rules to Control Noise Transmission

		Transmission
Noise Type	Noise Reduction Technique	Design Rules
Airborne	Enclosure	Use isolating panels lined inside with an absorbing material Minimize leaks Use silencers for functional openings (ventilation, rotating shafts, pipes, transport of material and parts) Avoid rigid connections between machine and enclosure
	Screen	Use isolating panels lined on the source side by an absorbing material Screens may be used when only a limited area has to be protected (workplace)
	Silencer	For broadband noise (medium and high frequencies) use absorption-type silencers For narrow-band noise (low and medium frequencies) use reactive-type silencers For compressed air discharge use pneumatic expansion silencers
Liquid borne		Use hoses instead of rigid pipes For broadband noise use accumulators For narrow-band noise use side-branch-type silencers
Structure borne	Isolation	For low frequencies use elements or layers that are more resilient than source and receiver For high frequencies add a heavy foundation between source and receiver
	Damping	Add damping only when the initial damping is low Apply damping near the source Use damping layers on thin plates only Damping of transmission can only be expected above the frequency of first bending mode

Table 3 Design Rules to Control Noise Radiation

		Radiation
Noise Type		Design Rules
Airborne		Optimize radiation directivity by placing the radiating openings in remote areas Fit the radiating openings with silencers or screens
Structure borne		Reduce the surface of radiating parts [see Eqs. (1) and (2)] Reduce radiation efficiency (decrease the thickness of plates or use perforated plates)

At this stage there is no more need for standardized methods but for some intuition! It is recommended to start with simple techniques and to increase complexity only if necessary. In the simple case of one dominating sound source and a small number of transmission paths and radiating parts, qualitative information may be sufficient to decide on the measures to be taken. In most cases however, it will be necessary to obtain quantitative information as well (i.e., the source strengths, transfer functions of transmission paths, radiation factors, etc.).

Typical escalation in complexity may be:

- Listening to noise (subjective impression, identification of tonal noise sources, etc.)

**Figure 6** Order of steps in the design and prototyping stages.

- Measurement of sound pressure levels in one or several points (noise mapping)
 - Linear or A-weighted levels
 - Spectra ($\frac{1}{1}$ - or $\frac{1}{3}$ -octave bands, narrow bands)
- Measurement of sound intensity levels for sound power determination on components
- Measurement of vibration levels
- Time records
- Analysis of combined quantities (impedance or mobility, coherence)

To limit the amount of work involved, it is useful to clearly define the purpose of each measurement step,

minimizing the amount of information where possible. For example, the use of one-third-octave spectra is often sufficient and practical.

Analysis of Noise Radiation As a first step it is recommended to start from the initial procedure (overall check) and to increase the resolution of analysis only at the basic measurement points:

In the Frequency Domain The measurement of some spectra already allows for detecting the frequency range(s) that are governing the overall noise level and on which noise reduction has to be focused. If the underlying physical principles of the machinery and of its components are known, the analysis of one spectrum may be sufficient to identify predominant internal sources. For example pure tones at characteristic frequencies of bearings, gears, pumps, fans, electric motors, and the like. Broadband noise due to flow or discharge of gases in valves and nozzles.

In the Time Domain When the noise emission is not stationary, it may be helpful to record sound pressure or other quantities as a time signal. This can be done for the overall level, a particular frequency band or for the whole spectrum ("waterfall"). Knowledge of the time history can give further insight into the NGMs and the involved components (impacts, sequences of different operations, etc).

In the next step it is useful to increase *spatial* resolution of analysis to get an idea of directivity and first information on transmission paths from the source to the boundaries of the machinery. A rough mapping of the global sound pressure levels around the machinery is carried out to determine areas of strongest emission. More thorough measurements, preferably made in the moderate near-field of the source (0.1 to 0.5 m), allow to identify radiating parts (openings, vibrating panels, noisy components...).

A powerful approach is given by sound intensity techniques, which allow precise information to be obtained even in the very near field of the source (0.05 to 0.20 m). These techniques include:

- Mapping of sound intensity levels (normal components)
- Determination of partial sound power radiated by specific areas of machine envelope
- Vector plots in different planes

An alternative technique is given by vibrational velocity measurements. This is recommended when:

- The acoustical environment is disturbed by strong or fluctuating background noise.
- Sources of aerodynamic noise are present in the machine. Then vibrational velocity measurements combined with airborne sound measurements allow to separate the different contributions from structure and air to the combined radiation.

Identification of Sound Sources If the noise radiation analysis has not yet allowed the identification of the predominant noise sources, several other techniques, summarized from Ref. 19 in Table 4, can be applied; they will supply mainly qualitative information. Quantification of vibroacoustic energy produced by the components may also be achieved by using structural intensity techniques according to Chapter 16.

Analysis of Transmission Paths It is necessary to distinguish between transmission of airborne, fluid-borne, and structure-borne noise. Propagation of *air-borne* noise is mainly observed:

- From inside to outside of casings, enclosures, and the like
- Through ducts (lined or not)
- Directly from a component to the machine environment.

All these paths are generally easy to detect and to characterize since input and output parameters can be measured by rather simple methods (sound pressure and/or sound power levels). When it is difficult to separate airborne and structure-borne contributions from a component, it may be recommended to use an artificial source, producing only airborne noise, instead of the machine component.

Fluid-borne noise propagation through pipes may be radiated directly by the piping but—since radiation efficiency of pipes is rather poor—the main problem is very often the structure-borne noise produced in connected structures (especially in lightweight structures such as thin plates). Measurements inside the fluid need special transducers and the interpretation of results is frequently complicated by strong standing waves.

The transmission paths of *structure-borne* noise are the most difficult to quantify since the input of structure-borne noise energy from a component to the machine structure is generally not known (it depends on both the source and the reception structure). Various isolation and/or damping techniques can be applied to the presumed transmission paths. When the radiated total sound pressure is measured before and after this operation, the difference illustrates the importance of the transmission path. These techniques are suitable only for the evaluation of major sound paths. In the case of unchanged results, it may be difficult to decide whether blocking was insufficient or if the considered sound path was not predominant.

6.3 Evaluation

The evaluation of the identified noise sources proceeds in three steps:

- Listing of all partial sound sources and their noise data (spectra of sound pressure, vibrational velocity, sound power, time records, etc.)
- Listing of corresponding transmission paths; rough estimation of partial energy transfers

Table 4 Techniques for the Identification of Partial Noise Sources

No.	Source Identification Technique	Pros	Cons
1	Switching off partial noise sources: The sound pressure as a function of frequency or time is measured on a normally running machine. Then measurements are made on the machine operated with one of the components switched off. The difference between both configurations shows the contribution of the switched-off partial noise source.	Simple instrumentation Arbitrary surroundings are allowed	Sometimes it is not possible to switch off the most relevant components. Even if it is possible, operating conditions of the machine may be altered.
2	Shielding of partial noise sources: Same approach as 1, but instead of switching off the particular component, only its noise emission is reduced. A partial airborne source, for example, may be shielded by an improvised enclosure. A partial structure-borne source may be isolated from the machine structure by improvised resilient elements.	Simple instrumentation Arbitrary surroundings are allowed	Needs changes at the machine.
3	Variation of operational parameters: Speed or load of the machine are varied and the radiated sound pressure is measured as a function of frequency or time.	Simple instrumentation Identification of partial sources is generally easier than in the case of constant operating condition Arbitrary surroundings are allowed	Variation is not always possible. Needs additional devices for the control of variation.
4	Signature analysis: On rotating machinery acceleration is measured at a point on the machine surface and synchronized with the signal of the rotating shaft. The analysis is carried out with special software.	Very suitable method to distinguish internal sources from the response of the machine structure	Special transducers and software are needed.
5	Correlation and coherence methods: The contribution of a partial source to the radiated total sound pressure is determined by analyzing the correlation between the total noise and a reference signal taken from the partial source.	No changes at the machine	Instrumentation is quite expensive. Sometimes it is difficult to get good reference signals.

- Ranking of contributions to the overall noise level

The planning of noise control measures should be guided by two main recommendations:

- Start with the predominant source, but do not forget that the sum of the remaining partial noise sources will limit all expected noise reduction! Therefore, it will generally be sufficient to reduce the noise level of a dominant component to approximately 5 dB below the residual level of the remaining partial noise sources. Further reduction of the dominant partial noise has only minor effects on the total noise.
- When there are several partial noise sources of approximately equal strength, the noise control measures must be applied to all these sources.

A noise reduction limited to selected individual noise sources will only have a marginal effect on the overall noise level.

6.4 Modification

The aim of this stage is to reduce individual contributions to the overall noise in the order of priority established in the evaluation stage. Since each contribution has been analyzed in terms of internal source, transmission path, and radiating part, in principle all these elements can be modified by noise control measures.

For some individual contributions the existing data may prove to be insufficient so that it is necessary to study more in depth mechanisms of excitation, transmission, and radiation (subbalance) before taking action on all three links of the noise generation chain.

In general, noise control measures are most effective when implemented close to the internal source. In

principle, the resulting order of priority should be that of the design stage, that is:

1. Internal source
2. Transmission through the structure
3. Radiating machinery parts

Since in practice the chosen strategy will not only depend on technical arguments but also on economical considerations, this order of priority may, of course, be modified.

Especially the size of the final product series will determine, for example, whether noise control measures are taken at the source (option to be considered in the case of big series) or if techniques based on enclosures are more suitable (small series or single machines). After each product improvement the priority list of major noise problems (see Section 6.3) must be updated to reflect the noise control measures taken.

CHAPTER 67

PSYCHOACOUSTICS AND PRODUCT SOUND QUALITY

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Throughout the twentieth century, engineers have used increasingly sophisticated experimental and theoretical approaches to reduce the noise of machines, vehicles, aircraft, and the like. Since the mid-1980s it has become apparent to manufacturers that it is insufficient simply to reduce overall noise levels. In most cases the noise of vehicles, appliances, and the like has been sufficiently suppressed so that it no longer poses a hearing loss hazard after extended exposure or interferes with speech, sleep, and other activities of occupants. Other properties of the noise, in addition to its overall sound pressure level, such as loudness, frequency content, tonal components, impulsiveness, and level fluctuations may determine whether the quality of the noise is acceptable or not in particular circumstances. Product sound quality studies have been made on household appliances, air-conditioning systems, and high-speed trains, for example, although most attention has been paid to interior vehicle noise.

2 BACKGROUND

In the late 1980s engineers began to realize that it is insufficient to pursue the one-dimensional goal of reducing the sound pressure level of the noise of a manufactured product. Attention began to be paid to the time structure and frequency content of noise in addition to its level. The noise output of the product and the auditory events it produces was recognized as being a multidimensional phenomenon. The term *sound quality* was coined.¹

More recently the term *sound quality* has become linked with the idea of *product quality* and specifically with a class of manufactured products, and the concept of *product sound quality* has been conceived. The discipline of *product sound engineering* has come into existence. Product sound quality may be defined as follows. *Product sound quality is a descriptor of the adequacy (or compatibility) of the sound associated with a particular product.* Product sound quality results from human judgments performed with reference to the desired features of the product, which are apparent to the users in their cognitive, utilization, and emotional situations.¹

Since the mid-1930s, filters have been used as a simple approach to obtain a quantitative measure that approximates the loudness of sounds. The A-weighting filter has been used extensively for such purposes.

Although it has proved extraordinarily useful, it is an insufficient measure of loudness since it has been derived from loudness judgments of moderately low-level pure-tone sounds at different frequencies, and it does not make allowance for the bandwidth and duration of the different sounds. Noises with the same A-weighted sound pressure level can, of course, sound quite different. If the sound pressure level is high, broadband, impulsive, and/or of a short duration, then use of A-weighting can be inaccurate and even sometimes quite inappropriate.

The majority of studies of sound quality have concentrated on the interior noise of vehicles, and most of the practical examples given in this chapter will be assumed to apply to this problem. It should be realized, however, that much of the discussion that follows may also be applied to other commercial machinery products and domestic appliances.

The goal of most modern sound quality studies is to try to quantify the sound quality of a particular product so that this can be used as a baseline for improving the sound quality of the existing product such as a particular vehicle model. The baseline can also be used for comparisons with the sound quality of other competing products. There are several ways with which quantification of sound quality can be undertaken: (1) exposing subjects to the product's noise under controlled conditions and having subjects evaluate different noise properties and/or rank and then quantify the rankings, (2) recording the product's noise using an artificial head and then asking subjects to evaluate the noise in controlled audiometric conditions with the use of earphones and/or dual loudspeakers in a special room, (3) recording the product noise binaurally with an artificial head and then presenting the noise to listeners with and without electronic modification of the noise to evaluate possible product sound quality improvements, and (4) recording the product noise binaurally with an artificial head and then evaluating the principal sound quality properties of the sound signature using purely electronic means.

This chapter first reviews psychoacoustics aspects of noise, which are important in sound quality evaluations. Then, procedures are outlined for evaluating sound quality using human subjects together with the design of different ways to rank or scale sound quality evaluations. Then, binaural recording of the product noise with an artificial head and playback to subjects

with and without electronic modification and some case histories of various sound quality investigations are described. Finally, evaluating the principal sound quality properties of the sound signature using purely electronic means is reviewed.

3 PSYCHOACOUSTICS

For any study of the sound quality of a product to be successful, it is important to have a good understanding of psychoacoustics. Psychoacoustics concerns the human auditory response to sound. To make psychoacoustics of most use in engineering studies, it is desirable to quantify human judgments of various properties of the sound that are most related to its quality. The sound must be presented to the listeners in a carefully controlled manner. Sounds are usually played to listeners either in the real-life situation such as in a moving automobile, or after suitable recording through two loudspeakers, or preferably via two earphones when the listeners are situated in a quiet audiometric room. Fastl has written useful reviews concerning the psychoacoustics needed to have a good understanding of sound quality.^{2,3} Several reference books are helpful in obtaining a good understanding of the fundamentals of psychological and physiological acoustics.⁴⁻¹⁴

3.1 Hearing Envelope

Figure 1 presents the auditory field for an average, normal young person who has not suffered any hearing loss or damage. The lower curve represents the hearing threshold, that is, the quietest audible sound at any frequency. The upper curve represents the discomfort threshold, that is, the sound pressure level at any frequency at which there is a sensation of discomfort and even pain in the ears. See also Fig. 1 in Chapter 21 and subsequent discussion there concerning discomfort and pain thresholds.

Speech is mainly in the frequency range of about 250 to 6000 Hz and at sound pressure levels between about 30 to 80 dB at 1 to 2 m (depending upon

frequency). Of course, the sound pressure level of speech can approach 90 dB at about 0.2 to 0.3 m from someone if they are shouting loudly. The sound of vowels is mostly in the low-frequency range from about 250 to 1000 Hz, while the sound of consonants is mainly in the higher frequency range of about 1000 to 6000 Hz. Music is spread over a somewhat greater frequency range and a greater dynamic range than speech. See Chapters 1 and 32. (The dynamic range represents the difference in levels between the lowest and highest sound pressure levels experienced.) See Chapter 35.

3.2 Loudness and Equal Loudness Contours

Sounds discerned to be louder than others are generally judged to be more annoying and less acceptable and thus of poorer sound quality. It must be noted that the human hearing mechanism does not judge different frequency sounds of the same sound pressure level to be equally loud.

Figure 2 shows equal loudness contours. The contours join the sound pressure levels of pure-tone sounds at different frequencies that listeners judge to be equally loud. Each curve is labeled with a number in *phons*, which is the value of each curve's sound pressure level at 1000 Hz. This is because such curves have been obtained by playing pure tones (normally of 1-s duration) at different frequencies to the listeners through earphones and asking them to adjust their sound pressure levels until they appear equally as loud as 1000-Hz pure tones played at the given sound pressure levels.

Figure 17 in Chapter 1 shows the A-weighting filter. This filter has approximately the same shape, except at very low frequency, as a smoothed version of the inverse of the 40-phon curve. Sound pressure level measurements obtained by prefiltering with the A-weighting filter have been used very often since the 1930s to give a single number approximation of human loudness. However, phon curves of higher levels are much flatter than the 40-phon curve and are not represented so well by the A-weighted sound pressure level. Also the A-weighting filter, although conveniently simple to use, has been derived from comparisons of pure-tone sounds at different frequencies. Thus it does not properly take into account the loudness of broadband sounds at different frequencies and the masking effect that these sounds have on each other. Another problem with A-weighting is that it does not allow for the fact that loudness increases with the bandwidth of the noise and also with the duration of the noise event for very short impulsive-type sounds of duration less than about 200 ms.

The concept of the critical band is of fundamental importance in psychoacoustics. It is of concern in studies of loudness, pitch, hearing thresholds, annoyance, speech intelligibility, masking and fatigue caused by noise, phase perception, and even the pleasantness of music. Figure 3 shows the loudness level of bands of filtered white noise centered at 1000 Hz as a function of bandwidth for the different constant sound pressure

Figure 1 Human auditory field envelope.

Figure 2 Equal loudness contours. The contours join the sound pressure levels of different frequency pure tones that are judged to be equally loud. The numbers on each contour are the loudness levels in phons.

Figure 3 Loudness level in phons of a band of filtered white noise centered at 1000 Hz as a function of its bandwidth. The overall sound pressure level of each band of noise was held constant as its bandwidth was increased, and this level is shown on each curve. The dashed line indicates that the bandwidth at which the loudness starts to increase is about the same at all of the levels tested, except for the lowest level for which no increase in loudness occurs. (From Ref. 15; used with permission.)

levels shown on each curve. The curves were obtained by a matching procedure in which listeners equated the loudness of a 1000-Hz pure tone with bands of noise

of increasing bandwidth. The level at which the pure tone was judged to be equal in loudness to the band of noise is shown as the ordinate. Thus the curves do not represent equal loudness contours, but rather they show how the loudness of the band of noise centered at 1000 Hz changes as a function of bandwidth. The loudness of a sound does not change until its bandwidth exceeds the so-called critical bandwidth. The critical bandwidth at 1000 Hz is about 160 Hz. (Notice that, except for sounds of very low level of about 20 phons, for which loudness is almost independent of bandwidth, the critical bandwidth is almost independent of level and that the slopes of the loudness curves are very similar for sounds of different levels.) (See Chapter 91 in the *Handbook of Acoustics*.^{15a}) Critical bands are discussed further in Section 3.4 of this chapter.

The solid line in Fig. 4 shows that sounds of very short duration are judged to be very quiet and to become louder as their duration is increased. However, once the duration has reached about 100 to 200 ms, then the loudness level reaches an asymptotic value. Also shown by broken lines in Fig. 4 are A-weighted sound pressure levels recorded by a sound level meter using the “impulse,” “fast,” and “slow” settings. It is observed that the A-weighted sound pressure level measured by the fast setting on the sound level meter is closest of the three settings to the loudness level of the sounds.

3.3 Masking

The masking phenomenon is well known to most people. A loud sound at one frequency can cause

Figure 4 Dependence of loudness level L_N (left ordinate) on duration T_i of 1-kHz tone impulses of constant sound pressure level compared with measurements of A-weighted sound pressure level L_A (right ordinate) using the time constants "impulse," "fast," or "slow."²

another quieter sound at the same frequency or a sound close in frequency to become inaudible. This effect is known as *masking*. Broadband sounds can have an even more complicated masking effect and can mask louder sounds over a much wider frequency range than narrow-band sounds. These effects are important in human assessment of product sound quality. Noise that contains pure tones is generally annoying and unpleasant. In the case of automobile interior noise, engine and exhaust system noise consists mostly of fundamental pure tones together with integer multiples and broadband engine combustion noise. Similarly cooling fan noise consists of pure tones and broadband aerodynamic fan noise. In the case of automobiles, exhaust and cooling fan noise have some strong pure-tone components. Wind noise and tire noise are mostly

broadband in nature and can mask some of the engine, exhaust, and cooling fan noise, particularly at high vehicle speed.

Figure 5 shows the masking effect of broadband white noise. The solid lines represent the sound pressure level of a pure test tone (given in the ordinate) that can just be heard when the masking sound is white noise at the level shown on each curve. For example, it is seen that white noise at 40 dB masks pure tones at about 55 dB at 100 Hz, 60 dB at 1000 Hz, and 65 dB at 5000 Hz.

The masking of noise has been studied extensively for more than 70 years. The curves in Fig. 5^{2,4} are very similar to those of much earlier research work by Fletcher and Munson in 1950 but are shown here since they have been extended to lower and higher frequencies than these earlier published results.⁹ One interesting fact is that the curves shown in Fig. 5 are all almost parallel and are separated by about 10-dB intervals, which is also the interval between the masker levels. This suggests that the masking of noise is almost independent of level at any given frequency. This fact was also established by Fletcher and Munson in 1950 as is shown in Fig. 6.¹⁶ Here the amount of masking is defined to be the upward shift in decibels in the baseline hearing threshold caused by the masking noise.⁹ Figure 5 shows that once the masker has reached a sufficient level to become effective, the amount of masking attained is a linear function of the masker level. This means, for instance, that a 10-dB increase in the masker level causes a 10-dB increase in the masked threshold of the signal being masked. It was found that this effect is independent of the frequency of the tone being masked and applies both to the masking of pure tones and speech.^{9,16}

Figure 7 shows the masking effect of a narrow-band noise of bandwidth 160 Hz centered at 1000 Hz. The curves in Fig. 7 join the sound pressure levels of test tones that are just masked by the 1000-Hz narrow-band noise at the sound pressure level shown on each curve. It is observed that the curves are symmetric around 1000 Hz for low levels of the narrow-band noise, while

Figure 5 Contours joining sound pressure levels of pure tones at different frequencies that are masked by white noise at the spectral density level L_{WN} shown on each contour.^{2,4}

Figure 6 Masking of tones by noise at different frequencies and sound pressure levels.¹⁶ Reprinted with permission from *J. Acoust. Soc. Am.*, 1950, Vol. 22, pp. 6–13, American Institute of Physics.

for high levels, the curves become asymmetric. It is seen that high levels of the narrow band of noise mask high-frequency tones much better than low-frequency tones. Figures 5 and 7 show that using either white noise or narrow-band noise it is more difficult to mask low-frequency than high-frequency sounds. This fact is of some importance in evaluating the sound quality of a product since it is of no use to reduce or change the noise in one frequency range if it is masked by the noise at another frequency.

There are other masking effects that are not normally as important for sound quality evaluations as the frequency effects discussed so far but still need

to be described.^{1–14} When a masking noise stops, the human hearing system is unable to hear the primary sound signal immediately. This effect is known as postmasking (and is sometimes also known as forward masking.) The time it takes for the primary sound to be heard (normally called the delay time, t_d) depends both upon the sound pressure level of the masking noise and its duration. Figure 8 shows how the primary sound is affected by different sound pressure levels of the masking noise. Also shown in Fig. 8 are dashed lines that correspond to an exponential decay in level with a time constant τ of 10 ms. It is observed that the human hearing mechanism decay is not exponential, but rather that it is nonlinear and that the decay process is complete after a decay time of about 200 ms. This fact is of practical importance since some vehicle and machinery noise is quite impulsive in character such as caused by diesel engines, automobile door closings, brake squeal, warning signals, or impacts that may mask the sounds of speech or other wanted sounds.

Figure 9 shows how sounds are affected by different durations of the masking noise. Figure 9 presents the level of a just-audible 2-kHz test tone L_T as a function of delay time.

3.4 Critical Bands

Another important factor is the way that the ear analyzes the frequency of sounds. The critical band concept already discussed in Section 3.2 is important here as well. It appears that the human hearing mechanism analyzes sound like a group of parallel frequency filters. Figure 10 shows the bandwidth of these filters as a function of their center frequency. These filters are often called *critical bands* and the bandwidth each possesses is known as its *critical bandwidth*.

As a band of noise of a constant sound pressure level increases in bandwidth, its loudness does not increase until the critical bandwidth is exceeded, after

Figure 7 Masking effect of a narrow-band noise of bandwidth 160 Hz centered at 1000 Hz. The contours join sound pressure levels of pure tones that are just masked by the 1000-Hz narrow-band noise at the sound pressure level shown on each contour.^{2,4}

Figure 8 Postmasking at different masker sound pressure levels.²

which the loudness continually increases. Thus the critical band may be considered to be that bandwidth at which subjective responses abruptly change.¹¹ It is observed that up to 500 Hz the critical bandwidth is about 100 Hz and is independent of frequency, while above that frequency it is about 21% of the center frequency and is thus almost the same as one-third octave band filters, which have a bandwidth of 23% of the center frequency shown by the solid line. (See Chapter 1.) This fact is also of practical importance in sound quality considerations since it explains some of the masking phenomena observed.

The *critical ratio* shown in Fig. 10 originates from the early work of Fletcher and Munson in 1937.¹¹ They conducted studies on the masking effects of wide-band noise on pure tones at different frequencies. They concluded that a pure tone is only masked by a narrow critical band of frequencies surrounding the tone, and that the power (mean-square sound pressure) in this band is equal to the power (mean-square sound pressure) in the

Figure 9 Postmasking of 5-ms, 2-kHz tones preceded by bursts of uniform masking noise are plotted as a function of the delay between masker and signal offsets. The parameter is masker duration T_m as indicated. The symbols are data from Zwicker.¹⁷ Reprinted with permission from *J. Acoust. Soc. Am.*, 1984, Vol. 75, pp. 219–223, American Institute of Physics.

tone.¹¹ From these assumptions the critical band can easily be calculated. From these assumptions, the critical bandwidth (in hertz) is defined to be the ratio of the sound pressure level of the tone to sound pressure level in a 1-Hz band (i.e., the spectral density) of the masking noise. This ratio is called the critical ratio to distinguish it from the directly measured critical band.¹¹ A good correspondence can be obtained between the critical band and the critical ratio by multiplying the critical ratio by a factor of 2.5. The critical ratio is given in decibels in Fig. 10 and is shown by the broken line.

Figure 10 Critical bandwidth, critical ratio, and equivalent rectangular bandwidth as a function of frequency. (○) Critical bandwidth from Zwicker¹⁸ is compared to the equivalent rectangular bandwidths according to a cochlear map function (---) (dashed line). (Based in part on Ref. 19.)

Figure 11 Relations between bark scale and frequency scale.^{2,4}

3.5 Frequency (Bark)

It is well known from music that humans do not hear the frequency of sound on a linear scale. A piano keyboard is a good example. For each doubling of frequency (known as an octave), the same distance is moved along the keyboard in a logarithmic fashion. If the critical bands are placed next to each other, the bark scale is produced. The unit *bark* was chosen to honor Barkhausen. Figure 11 illustrates the relationship between the bark (Z) as the ordinate and the frequency as the abscissa; on the left (Fig. 11a), frequency is given using a linear scale, and on the right (Fig. 11b) the frequency is given with a logarithmic scale. Also shown in Fig. 11 are useful fits for calculating bark from frequency. At low frequency a linear fit is useful (Fig. 11a), while at high frequency a logarithmic fit is more suitable. (Fig. 11b).

One advantage of the bark scale is that, when the masking patterns of narrow-band noises are plotted against the bark scale, their shapes are largely independent of the center frequency, except at very low

frequency. (See Fig. 12.) Care should be taken to note that the ear does not hear sounds at a fixed number of fixed center frequencies as might be suspected from Fig. 12. Rather at any frequency f_m considered, the average ear has a given bandwidth.

3.6 Zwicker Loudness

The loudness of sounds was discussed in Section 3.2 where it was shown that A-weighted sound pressure level measurements underestimate the loudness of broadband noise. (See Fig. 3.) Methods to evaluate the loudness of broadband noise based on multiband frequency analysis have been devised by Stevens,²⁰ Kryter,¹⁴ and Zwicker.²¹ The Stevens' method was originally based on octave band analysis, but Kryter's and Zwicker's methods are based on one-third octave band analysis. Kryter's method has been standardized for aircraft certification noise measurements, while Zwicker's method has been standardized internationally and is most normally used to evaluate the

Figure 12 Masking patterns^{2,4} of narrow-band noises centered at different frequencies f_m .

Figure 13 Schematic illustration of Zwicker's loudness model.²⁻⁴

Figure 14 Illustration of temporal effects in loudness processing.^{2,4}

loudness of many common sound sources including speech, music, machinery, and vehicles.

The procedure to evaluate loudness using Zwicker's method is shown in Fig. 13. Figure 13a shows a narrow band centered at 1000 Hz, which corresponds to 8.5 bark. Figure 13b shows the narrow band of noise at 1000 Hz, including masking effects caused by spectral broadening in the cochlea due to inner

ear mechanics. Figure 13c shows the specific loudness/critical band rate pattern (sone/bark), known as the *Zwicker diagram*. The transition from the masking pattern in Fig. 13b to the loudness pattern in Fig. 13c can be considered to be obtained by simply taking the square root of the sound pressure or the fourth root of the sound intensity. The shaded area in Fig. 13c is directly proportional to the perceived loudness.

While Fig. 13 illustrates the spectral process of obtaining the perceived loudness of a sound by the Zwicker method, Fig. 14 shows the process including temporal effects. Figure 14a shows two impulses in the time domain, one with a broken line of 10-ms duration and the other with a solid line of 100-ms duration. As discussed earlier in connection with Fig. 3, very short duration pulses of noise are perceived to be quieter than longer ones up to a duration of about 100 to 200 ms. Figure 14 is constructed by assuming that the hearing mechanism behaves like a parallel bank of 24 critical band filters. Figure 14b represents the processing of the loudness in each of the 24 channels of an empirical *loudness meter* used to model the hearing mechanism. Finally, Fig. 14c shows the time dependence of the total loudness summed up over all 24 channels of the empirical loudness meter. Figure 14b shows that the short 10-ms tone burst decays much more rapidly than the 100-ms tone burst. The results shown in Figs. 13 and 14 are important in evaluating the sound quality of machinery that has impulsive noise components, such as diesel engines and machines in which impacts occur.

3.7 Loudness Adaptation

The term *loudness adaptation* refers to the apparent decrease in loudness that occurs when a subject is presented with a sound signal for a long period of time. The effect has been studied extensively by presenting tones for an extended period of time to one ear and then allowing the subject to adjust the level of a second comparison tone of the same frequency to the other ear. Such experiments have demonstrated

that loudness adaptation of as much as 30 dB can be observed for very quiet sounds below 30 dB and much less for louder sounds of the order of 70 dB. However, other research has shown that loudness adaptation is reduced or even absent when binaural interactions are minimized. Recent research has shown that loudness adaptation is quite complicated. It varies from person to person. More adaptation occurs for very quiet sounds of about 30 dB and for high-frequency tones than for low-frequency tones or noise.⁹ This phenomenon is obviously of interest to those concerned with sounds such as interior vehicle noise, that people experience over an extended period.

3.8 Empirical Loudness Meter

Figure 15 shows a block diagram of an empirical Zwicker-type dynamic loudness meter (DLM) that includes the spectral and temporal loudness processing portrayed in Figs. 13 and 14.³ First, the *spectral processing* (1 and 2) shown in Fig. 14 using the critical band filter bank concept, *upward spread of masking* (7), and *spectral summation* (8) are illustrated. Second, the *temporal processing* discussed in relation to Fig. 14 is observed as shown in the blocks marked *envelope extraction*, *postmasking*, and *temporal integration* (see steps 3, 6, and 9.) Lastly and of most importance is step 5 (labeled *loudness transformation*), which represents the fact that the loudness is assumed to be proportional to the square root of the sound pressure (or the fourth root of the sound intensity. (See Fig. 13c.)

One advantage of the DLM discussed and shown in Fig. 15 is that, by suitable modification of the DLM

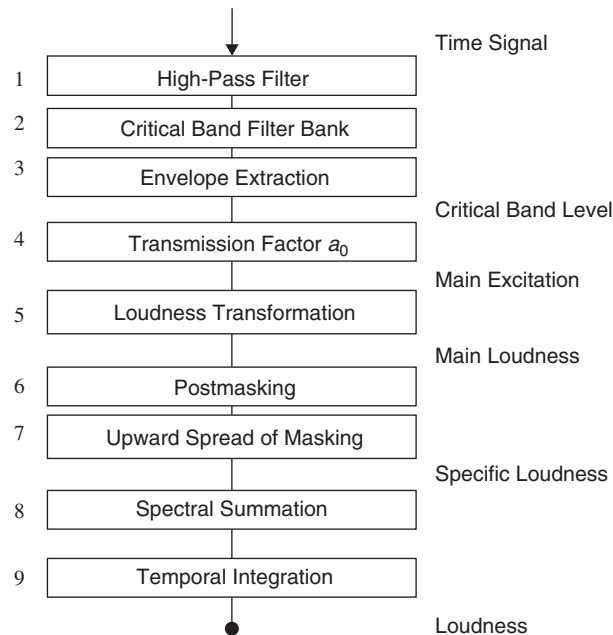

Figure 15 Block diagram of the dynamic loudness model (DLM).⁷²

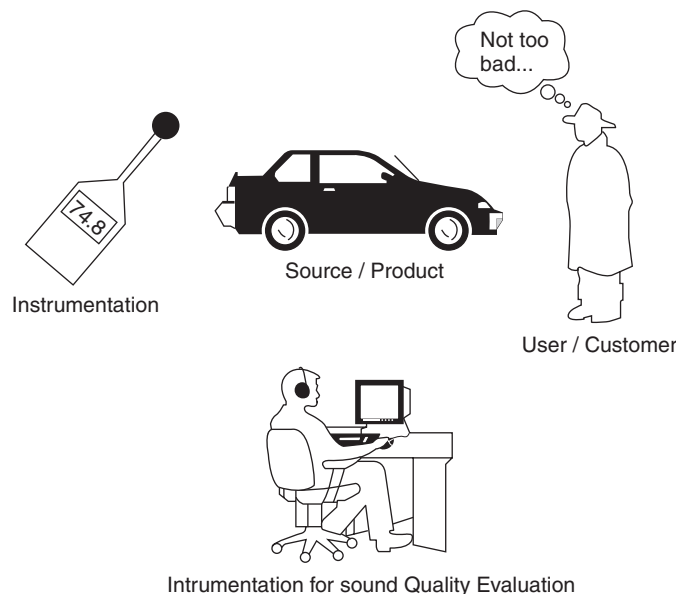

Figure 16 Sound quality evaluation by humans (*right*), standard instrumentation (*left*), and instrumentation for sound quality evaluation (*bottom*).²⁷

loudness transformation (step 5), the loudness perception of both normal hearing and hearing impaired subjects can be simulated.³ This fact is important since the aging population in industrialized countries has suffered varying degrees of hearing impairment that should be allowed for in sound quality simulations. Some fraction of the younger population may have suffered mild to moderate hearing loss because of exposure to intense noise during recreational or leisure time activities.³

4 SOUND QUALITY EVALUATION

Whenever we listen to the sound of a mechanical product, we form an opinion about its sound quality. (See the right side of Fig. 16.) Our reactions may be, to some extent, unconscious and our opinions influenced by visual impressions, other cues and expectations, and by previous experience.

While a single measurement of the A-weighted sound pressure level may be an adequate measure of the product for regulatory purposes (see the left side of Fig. 16), more elaborate approaches and measures are required for sound quality evaluations. (See the bottom of Fig 16.) Such sophisticated procedures for sound quality assessments and use of dedicated instrumentation have the advantage that (1) experiments can be carefully controlled and standardized so that they can be repeated by others, (2) different attributes of the product's sound signature can be properly evaluated, and (3) the product's sound signature information and measured results can be used to modify and/or redesign its sound signature as necessary.

Subjective evaluation of the sound quality of a product is normally found by exposing a panel of

listeners, or a jury, to the sound of the product and then asking them to make individual subjective responses on an appropriate scale, which are then averaged. Such evaluations usually consist first of the measurement and recording of the sound of the product. This is followed by the subjective ratings of the jury of the original recording and then of a suitably processed recording of the sound (either monaural or binaural). For example, by editing out a particular tone or part of the spectrum, it is possible to determine whether or not the edited version of the sound improves the perceived sound quality of the product. If the sound quality is improved by such changes, then engineering modifications can be sought to accomplish the new sound signature by quieting and/or appropriately modifying the responsible noise source(s).

Various psychoacoustic metrics such as loudness, noisiness, sharpness, and fluctuation strength have been developed to assist in predicting sound quality. Some researchers such as Lyon believe that these psychoacoustic metrics, although useful in scaling certain features of the sound of a product, still need further development to predict the acceptability of the sound quality of a product. Consequently, Lyon suggests that emphasis should currently be concentrated on the determination of sound quality through the assessment of subjective jury evaluations.²²⁻²⁵

Otto et al.²⁶ and Fastl³ have discussed the use of jury tests to evaluate the sound quality of products, in particular automobiles. There are several different types of jury tests that have been used for many years to evaluate the sounds of different products, such as loudspeakers, electric clocks, and other appliances. In recent years these jury tests have been adapted for

use in evaluating the sound quality of automobiles. A jury test means that the test is conducted using a group of individuals instead of just one. There are a large number of jury tests in use in sound quality evaluations. We will concentrate here on some of the most common tests.^{3,26}

4.1 Paired Comparison Tests

Paired comparison tests involve the presentation of two sounds to each human subject. The subjects are then asked to give relative judgments on the sounds of each pair.²⁶ Various relative sound evaluations can be made. Three of these will be described here. First, in a *detection task* the subject is asked to decide which of the two sounds contains the signal to be detected. This type of test is useful to determine detection thresholds of a sound signature, for example, if a discrete frequency (tone) is buried in broadband noise. Second, an *evaluation task* involves the subject evaluating which pair of sounds possesses more or less of a certain attribute such as loudness, annoyance, pleasantness, and the like. Lastly, a *similarity task* requires the subject to decide which of the pairs of sounds are most similar to each other. This type of task can be used, together with multidimensional analysis and clustering studies, to determine which properties of a sound signature are important and/or unimportant in forming reliable judgments of the sound quality of a product.²⁶

4.2 Random-Access Ranking Procedure

In the random-access ranking procedure, the subject is asked to rank order N sounds from 1 to N , where N is the number of sounds.²⁶ This is one of the simplest sound quality evaluation procedures. It largely avoids the biasing that some of the other procedures may produce. Although the sounds are presented in an initial sequence, the subject is allowed to access each sound as many times as desired by clicking an icon, such as the loudspeaker icon in Fig. 17, and eventually to form a final judgment. To avoid too much complexity in the task, the number of sounds to be compared and ranked is normally kept to be less than five or six.^{3,26} The freedom of the subject to choose the sounds in some random fashion and thus eliminate the influence of the person conducting the test makes this procedure preferred by many testing organizations. It does have the disadvantage, however, that since there is no scale obtained in the final result, that the sounds cannot be correlated with any objective sound quality attributes in the final analysis.²⁶

4.3 Semantic Differential Procedure

While the paired comparison test only considers one attribute, the semantic differential procedure considers many different attributes of a sound. The subject is asked to evaluate a sound signature using a number of bipolar pairs of adjectives as shown in Fig. 18. The two adjectives are normally antonyms and lie at the two ends of a scale with several gradations. Usually,

Figure 17 Example for ranking of the sound quality by the method random access.

Adjective Scales	
Loud	Soft
Deep	Shrill
Frightening	Not Frightening
Pleasant	Unpleasant
Dangerous	Safe
Hard	Soft
Calm	Exciting
Bright	Dark
Weak	Powerful
Busy	Tranquil
Conspicuous	Inconspicuous
Slow	Fast
Distinct	Vague
Weak	Strong
Tense	Relaxed
Pleasing	Unpleasing

Figure 18 Semantic differential scale.⁷²

five, seven, or nine gradations are used between each adjective pair.^{3,8}

4.4 Category Scaling

Category scaling is often used when one attribute such as loudness needs to be evaluated.²⁶ Figure 19 shows a 5-step scale on the left and also a 7-step scale in the middle. In the middle of Fig. 19, the 7-step scale is further subdivided into 10 or more subcategories on the right, if a finer loudness evaluation is desired.³

4.5 Magnitude Estimation

In the magnitude estimation procedure, two sounds are compared.^{3,26} One of the sounds, A, is fixed and normally termed the anchor sound. The magnitude of the second test sound, B, must be decided by the subject. Usually loudness is chosen as the attribute to be considered, but another attribute such as annoyance can be chosen instead. The anchor sound, A, is usually given a value such as 100, and the subject is asked to evaluate the test sound and to give it a relative ranking greater or smaller than the anchor sound. The advantage of this procedure is that there is no ceiling fixed for the test sound.

Figure 19 Category scaling with five categories (left), seven categories (*middle*), and 10 subcategories (right).

5 RECORDING AND PLAYBACK

Recording of the product sound to be evaluated is often undertaken for later evaluation and product sound quality improvement. It is important to note that, for proper reproduction of product sound signatures, binaural recordings should be made. Most researchers emphasize the fact that single-channel recordings are normally inadequate, and binaural recordings are preferred for sound quality evaluations. Great care must be taken with such sound recordings so that distortion is avoided and that the reproduction of the sounds presented to the subjects is as faithful as possible to the original. For this purpose, microphones are sometimes located in both ear canals of a human subject and/or at both the eardrum positions of an artificial head. In playback, care must be taken to maintain the proper magnitude and phase difference between the two channels. Since the head, pinna, ear canal, and torso geometries and properties vary from person to person, dummy heads can only be made to represent statistically averaged geometries and properties of people. Several different dummy heads are available commercially, and they are made to meet standards such as International Electrotechnical Commission (IEC) 959, in which basic human characteristics are defined. Figure 20 illustrates the fact that during playback the subject must be able to sense that the sound source is in the same physical location as during the initial recording.²⁷

For very low frequency product sound signatures, multichannel recordings may become necessary. At very low frequency, the sound is sensed by the human body as vibration as well as sound sensed by the ears. In cases where significant low-frequency components are present in the sound signature, some attempts have been made to give a realistic feeling for these components by the use of additional bass loudspeakers or woofers.²⁷ Some commercially available software tools allow for multichannel recordings not only of the binaural sound recordings, but of engine revolution/minute (rpm), vehicle speed, air temperature, and the like.

Figure 20 Principle of binaural recording (*top*) and playback (*bottom*). In ideal conditions the different auditory events in the recording situation (*top*, filled circles) are perceived in the playback situation at exactly the same locations (*bottom*, open circles). Under nonideal circumstances different aspects might result in localization errors.²⁷

It is normal procedure to convert the sound signals acquired from analog to digital form and then to store them on digital tape or more commonly directly onto a computer hard drive. These signals can then be played back to subjects through loudspeakers or earphones. Earphones are generally recognized as providing a more realistic representation of the original product sound. Recorded signals can also be analyzed, processed, and modified and then played back to subjects in modified form to try to determine the properties and qualities of the product sound signature that makes the sound more acceptable and pleasant for subjects. Many attempts have also been made to

Figure 21 Pool of psychoacoustic quantities.²⁷

analyze the recorded sounds and then, without the use of human subjects, to try to identify the most important properties of the sounds that contribute to sound quality.

Although A-, B-, and C-weightings give some initial impressions of the loudness and frequency content of a sound, are simple to use and are well known, they are generally recognized as being inadequate for sound quality research.²⁷ As already discussed, sound pressure level, loudness, frequency content, level fluctuation, pure-tone components, and impulsiveness are known to be important attributes of the quality of sound.

Auditory events can be broken down arbitrarily into a set of main categories. Figure 21 illustrates some of the psychoacoustical properties of sound that are known to affect sound quality. Of these, loudness, roughness, and sharpness are thought to be some of the most important properties in the case of automobile sound. Unfortunately, the quantitative calculation of most of these sound quality properties has not been internationally agreed upon, with the exception of Zwicker loudness.^{2,3}

In most sound quality work, a target sound is chosen for the product. Efforts are then made to design and modify the product to achieve the target sound. See Fig. 22. Editing of the sound using filtering and other techniques, use of subjective sound quality evaluations, and suitable changes are made to the physical characteristics of the source in an attempt to achieve the target sound as shown in Fig 23.

Hardware and software have been developed to try to evaluate and calculate some sound quality attributes only by the use of signal processing of the sound signature of the product. Some specific hardware systems for sound quality calculations exist. It is possible, however, simply to operate some other commercially available software systems on most standard personal computers.²⁷ Both closed and open software systems exist. Some *stand-alone* systems, which are commercially available, include fixed procedures for the calculation of the sound quality properties, such as loudness, roughness, sharpness, and the like, and

Figure 22 Target setting for sound quality.²⁸

that do not allow these calculation procedures to be changed. Other systems are classified as *semiopen* and allow some formulas to be imported for calculations of some of these quantities. There are also systems, classified as *completely open*, that allow all of the calculation procedures for these properties to be imported. So far international organizations have only agreed upon the loudness property calculation.

Instrumentation and software for sound quality evaluation is still under continuous development. Some companies and institutes involved in sound quality research use their own software and methods

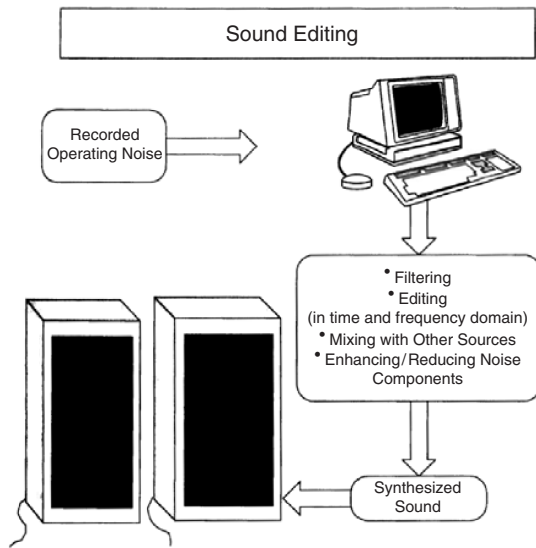

Figure 23 Simulation of “preferred sound” by editing the recorded operating noise.²⁸

to calculate sound quality. Others use commercially available software.

6 FURTHER PSYCHOACOUSTIC QUALITIES

6.1 Sharpness

If the sound of a product has the right amount of *sharpness*, it can sound powerful; but if it has too much sharpness, it can sound harsh and unpleasant. As the word suggests, *sharpness* is a measure of the high-frequency content of sound. If one sound signal has more high-frequency content than another, it is said to have more *sharpness* than the other.

Figure 24 gives an indication of the dependence of sharpness on frequency content; the solid line represents the sharpness of narrow bands of noise with bandwidths of 1 bark.^{2,3} The perceived sharpness is seen to increase as the band center frequency is increased. The broken line in the upper part of the figure shows the sharpness of high-pass filtered noise as a function of cutoff frequency, while the dotted curve presents the perceived sharpness of low-pass filtered noise as the cutoff frequency is changed. As shown by the upper broken curve, when the cutoff frequency of the high-pass filtered sound is decreased, the sound has reduced sharpness and sounds less harsh. This has implications for the sound quality of products. If some low-frequency sound is added to a harsh sounding product, the resulting sound will normally sound less harsh.⁷ Of course, the loudness level of the resulting product sound will increase as well to some extent, but that may be acceptable if the product's loudness level is not very high at the outset. As the dotted curve shows, when the cutoff frequency of low-pass filtered noise is increased, it sounds sharper and it will, of course, also sound louder.

Figure 25 shows a model for sharpness. In Fig. 25a, the spectral distribution of a narrow-band noise (solid line), a broadband noise (broken line and dashed area), and a high-pass filtered noise (dotted line and cross-hatched area) are shown. The sharpness model corresponds to Fig. 13. In Fig 25b, the arrows indicate the center of gravity of the loudness patterns.^{2,3} The higher frequencies are perceived to have more sharpness and are boosted by a weighing function, g .

6.2 Fluctuation Strength

Another important psychoacoustic attribute is fluctuation strength. Sound that has a strong time-dependent fluctuation in sound pressure level, L_T , is more annoying than sound that has a steady sound pressure level. Experiments show that the fluctuation strength,

Figure 24 Sharpness of narrow-band noise (solid), high pass noise (dashed), and low-pass noise (dotted).²

Figure 25 Model of sharpness for narrow-band noise (solid), broadband noise (dashed), and high-pass noise (cross hatched).^{2,3}

F , possesses a bandpass character and has a maximum value for sounds with a modulation frequency of about 4 Hz. This fact is true for both amplitude and frequency-modulated sounds.^{2,3} The fluctuation strength depends upon the modulation depth, ΔL , and sound pressure level L_T . If the modulation depth is less than 3 dB, the fluctuation strength is zero. The fluctuation strength increases approximately linearly for greater values of L_T . For a level increase of about 40 dB, the fluctuation strength increases by a factor of 3. More details of fluctuation strength estimation are given by Zwicker and Fastl in Ref. 2 and 4.

One formula used to calculate the fluctuation strength, F , is given in Fig. 26. The hatched areas within the thin solid lines represent the time-dependent variation of the sound pressure level of the sound. The thick solid line represents the time-dependent masking pattern. Because of postmasking effects, the ear is unable to hear the sound properly in the very “quiet” valleys. So far no universal agreement has been obtained on this or any other formula for the calculation of fluctuation strength.

6.3 Roughness

If the modulation time period $1/f_{\text{mod}}$ becomes very small, and the modulation frequency is more than about 20 Hz, the fluctuating strength is termed roughness as is shown in Fig. 27. The roughness of a sound

is found to be a maximum when the modulation frequency is about 70 Hz. This is true for both narrow-band and broadband sounds. Roughness depends upon the modulation depth, ΔL , and sound pressure level L_T . An approximate relationship for roughness, R , is also given in this figure. For a level increase of 40 dB, the roughness increases by a factor of about 3. The roughness also increases with the sound pressure level L_T . More details about roughness calculations are given by Zwicker and Fastl in Refs. 2 and 4.

7 EXPERIMENTAL AND SYNTHESIS RESULTS

Further work continues on sound quality research using jury evaluations and electronic modification, synthesis, and evaluation of sound product signals.^{26,29-74} A considerable amount of research on this subject has been conducted in Germany.^{1-3,27-37} Most of this research work has concentrated on interior vehicle sound quality. Researchers in many other countries have also conducted research on vehicle sound quality³⁸⁻⁶² or on the sound quality of vehicle components, such as exhaust systems,⁴¹ transmissions,^{42,43} doors,⁴⁴ and on specific attributes of vehicle sound quality. Some others have conducted sound quality studies on off-road vehicles⁶² and electric vehicles,⁶³ appliances, or industrial and other equipment,⁶⁴⁻⁶⁷ telephones,⁶⁸ and vacuum cleaners.⁶⁹ Other researchers have concentrated

Figure 26 Model for fluctuation strength.²⁻⁴ (a) Envelope of amplitude-modulated sound (hatched) with corresponding temporal masking pattern (solid) and (b) basic formula for fluctuation strength F .

Figure 27 Model of roughness.²⁻⁴ (a) Envelope of amplitude-modulated sound (hatched) with corresponding temporal masking pattern (solid) and (b) basic relationship for roughness R .

on external vehicle sound quality.⁴⁶⁻⁴⁸ Some other researchers have studied specific attributes of sound quality, including rumbling and booming.⁵²⁻⁶¹

7.1 Results of Jury Tests

Figure 28 shows results of sound quality evaluations on a diesel engine.³ The engine studied can be run in a “hard” setting as in Fig 28a or “normal” setting as in Fig 28b. In the hard setting the engine is more fuel efficient but makes more noise and this noise sounds “harder” and more unpleasant. Figure 28a shows sound quality rank assessments made with the engine running first in its hard setting. The subjects

were asked to evaluate the engine noise as the high-frequency part of the sound spectrum (1 to 5 kHz) was reduced in 3-dB steps up to an attenuation of 15 dB. The circles represent the sound quality ranks assigned to the sounds by the human subjects. The crosses represent predictions of the maximum loudness N_{max} made using a software calculation. The ranking 1 represents the best sound quality and quietest sound and 12 represents the worst sound quality and loudest sound. The motor with the unfiltered hard setting received the poorest sound quality (SQ) rankings of 12. Figure 28b shows the improvement in the sound quality and loudness rankings for the same

Figure 28 Improvement of the sound quality of a diesel motor with “hard” motor adjustment and simulated absorptive measures that cause different amounts of attenuation. Circles denote subjective human subject sound quality estimates. Crosses mark loudness predicted from acoustical measurements.³

diesel motor running in its normal setting as different amounts of attenuation were used over the whole frequency range. The electronic attenuations of the sounds were made to simulate the motor sound, which would be heard with different amounts of attenuation achieved by engine enclosure and/or use of sound absorption treatment.

It is observed that in Fig. 28a after the sound was attenuated by 15 dB from 1 to 5 kHz, a sound quality ranking of only 7 was achieved, although the loudness N_{\max} was 4. The sound quality is poorer than the unattenuated normal "series" motor in Fig. 28b, in which the sound quality is 4 and the loudness is 7. It is seen that there is a general agreement in the trends of sound quality SQ and loudness N_{\max} rankings with increasing attenuation in Figs. 28a and 28b. Exceptions to the good agreement, however, exist for cases of (1) the sound quality and N_{\max} for the 15-dB attenuated sound in Fig. 28a and (2) the normal series motor in Fig. 28b. This demonstrates the fact that although loudness is a very important component, it is not always an adequate or completely reliable indicator of sound quality.^{2,3}

Figure 29 shows the results of semantic differential jury evaluations made at the Sound and Vibration Research Laboratories at Auburn University on the interior sound of four automobiles. The four vehicles studied included a 2003 Jaguar S-type luxury car, a 2005 Acura sports sedan, a 1988 Porsche 911 Carrera sports car, and a 2005 sports utility vehicle (SUV). The vehicles were driven in steady cruise conditions at 63 km/h, and the interior noise in each vehicle was recorded binaurally directly onto the hard drive of a laptop computer using a dummy head, which was located in the passenger seat position. The A-weighted sound pressure levels were measured in each vehicle with a precision sound level meter. The recorded vehicle sound signatures were played back over two loudspeakers at the same A-weighted sound pressure level as recorded in the vehicles as illustrated in Fig. 23. Figure 29a shows the mean of the 27 subject evaluations of the Porsche sports car and the Jaguar luxury car. Figure 29b shows the mean evaluations of the SUV and Acura sports sedan car. The subjects listened to the vehicle recordings in a randomized order and were not informed which four vehicle recordings were being presented to them during the test. It can be seen that the sports car is rated much more noisy, rough, ugly, dull, and powerful than the luxury car. The SUV and sports sedan car received surprisingly similar mean evaluations from the subjects. Both of these cars were only about one year old.

7.2 Meaning of Sound

The majority of sound quality metrics can be divided into those that quantify some physical aspect of the sound (e.g., pressure level, frequency content) and those that try to quantify some physical effect taking place in the ear (e.g., impression of loudness, tone, etc.). In the first case, we assume that a particular physical measure of the sound is always going to produce

Figure 29 Semantic differential evaluations for interior car sounds cruising at 63 km/h of a sports car, luxury sedan, SUV, and an economy sports sedan: (a) Porsche sports car, ■ — ■, and Jaguar, • - - •, and (b) Acura, ■ — ■, and SUV, • - - •.

a particular physical effect, and in the second case we assume that a particular physical effect is always going to produce a particular cognitive response. This model allows us to replace a human subject with a calculation system for some metrics once knowledge of the cognitive reactions is established. This approach has the obvious weakness that the assumptions are invariant as the following case demonstrates.

Figure 30 shows the results of the response of German and Japanese subjects to the sound of a bell.⁷² The sound signal was perceived as being safe and pleasant by the German group and dangerous by the Japanese group. This was thought to be because most Japanese subjects associated the sound as a warning of the approach of a fire engine, while the subjects in the German group mostly associated the sound with church bells.

Recent research conducted to examine how the perceived meaning of a sound affects the judgment of sound quality has been carried out using an algorithm designed by Fastl and co-workers to remove the subjects' ability to identify a sound. The research

Figure 30 Evaluations of the sound of a bell by Japanese, —●— and German - -◆- - subjects.⁷³

work assumes that discrepancies will exist between subjective judgments of identifiable and nonidentifiable sounds that have the same objective metric values. It also suggests that these differences will be due to the perceived meaning of the sound.⁷⁰⁻⁷² Fastl and others have now tried to remove the identifiability of the sounds by reversing them in the time domain and by other means.⁷⁰⁻⁷² Such signal time reversal can preserve the frequency content of the sound but largely remove its identification cues.

7.3 Other Differences Biasing Evaluations

Kuwani et al. have also reported semantic differential evaluations of the noise in passenger cars made by different groups of subjects.⁷³ Fourteen pairs of adjectives were used in the evaluations. The adjective pairs were presented in random order to the subjects. The subjects came from 21 countries. The interior cabin sounds of 5 kinds of accelerating noise were used as stimuli. The sounds were presented to people using earphones in a "soundproof" room. There were 21 female and 36 male subjects between the ages of 13 and 69. Comparisons were made between male and female subjects, between younger and older subjects (below and above the age of 39), and between U.S. and European subjects in the evaluations of the sound. In general, the younger subjects and the male subjects tended to evaluate the sounds close to the average of the whole group of 39 subjects, while the older and female subjects exhibited evaluations that were somewhat different. Figure 31 shows the different results for the American and European subjects. In this particular test there were 17 Americans and 18 Europeans. Both groups found stimulus 2 as unpleasant and stimulus 4 as being more acceptable.

However, the Americans found stimulus 2 more ugly, harsh, loud, unpleasant, strident, and rough than the Europeans.

7.4 Results of Sound Synthesis Tests

Some researchers have conducted a considerable amount of research on two additional sound quality indicators, commonly called *booming* and *rumbling*. No international agreement has been reached on rumbling and booming indices. However, a proposal has been published for a booming index.⁵³

Lee has described the results of some psychoacoustic experiments on the rumbling sound index for cars.⁵⁴ The index he used is based on several previous studies involving subjective evaluations of the sounds of vehicles. The conclusions of these studies showed that the rumbling sound quality can be related mostly to three qualities: the principal rumble component, loudness, and roughness. Based on this previous experimental work, a large number of synthetic interior sounds with different rumbling components were constructed electronically. Figure 32 shows a synthetic sound wave with a rumbling character. Figure 32a displays the time history of the amplitude-modulated wave formed by three half-order components used for the production of the rumbling sound. Figure 32b shows the spectrum of this amplitude-modulated wave. Finally Fig. 32c shows the principal component of the amplitude-modulated wave.

Figure 33 shows waterfall analysis of the interior sound of a passenger car as a function of engine rpm. Figure 33a shows the interior basic sound without the rumbling sound added, and Fig. 33b shows the modified sound with the rumbling sound added.

Altogether 240 different rumbling sounds were produced by varying the rumbling amplitude and the

Figure 31 (a) U.S. (squares) and European (circles) of stimulus vehicle 2 and (b) U.S. (squares) and European (circles) evaluations of stimulus vehicle 4.

Figure 32 Synthetic sound waves with rumbling sound quality: (a) amplitude-modulated wave formed by three half-order components used for the production of a rumbling sound, (b) spectrum of the amplitude-modulated wave, and (c) principal component of the amplitude-modulated wave.⁵⁴

rumbling frequency as in Fig. 32. These rumbling sounds were then added to the basic vehicle sound to create 240 synthetic interior sounds for evaluation by the human subjects.

Before the 240 synthetic sounds were evaluated, 84 non-rumbling-like sounds were removed, and the interior sounds of 14 mass-produced passenger cars were added to the group, making a total of 170 interior sounds for evaluation by the subjects. The sounds were evaluated also using four sound quality units: loudness, sharpness, fluctuation strength, and roughness. The units of sharpness S (acum), fluctuation strength F (vacil), and roughness R (asper) are discussed by Fastl in Ref. 3 and further details and their definitions are given by Zwicker and Fastl in Ref. 4.

Figure 34 presents sound metrics for the 170 passenger car interior rumbling sounds. Figure 34a shows the loudness for the sound signals, evaluated using Zwicker's method, plotted against the subjective ranking of the sounds. The loudest sound has a value of about 17 sones and an average subjective ranking of about 5.5. The results of Fig. 34a indicate that the subjective ranking is equal approximately to the inverse of the loudness. Figure 34b displays the roughness of the 170 interior sounds calculated using Bismarck's model, plotted against their subjective rankings. The roughness is related to the amplitude modulation and frequency modulation as explained in Section 6.3 and Fig. 27. The maximum roughness is about 0.4 asper at a subjective ranking of 5.5. The relationship between the subjective ranking and roughness is not very clear. Figure 34c shows the sharpness for the 170 interior sounds, calculated using Aures' model. The maximum sharpness is seen to be about 0.5 acum at a subjective ranking of about 5.5. However, for most of the sounds, the sharpness is about 0.45 acum, and there is no clear relationship between the subjective ranking and the sharpness. Finally Fig. 34d shows the fluctuation strength for the 170 interior sounds calculated using Fastl's model. The fluctuation strength is described in Section 6.2 and Fig. 26, where the fluctuation strength is shown to be related to the amplitude modulation and frequency modulation in the region of 4 Hz. In Fig. 34d the

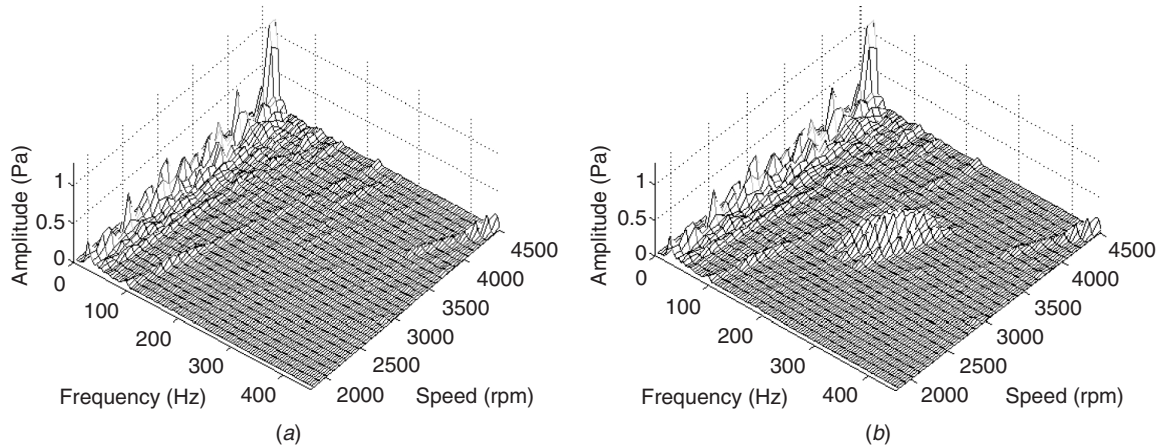

Figure 33 Waterfall analysis for interior sound of a passenger car: (a) base sound and (b) modified sound with rumbling sound quality.⁵⁴

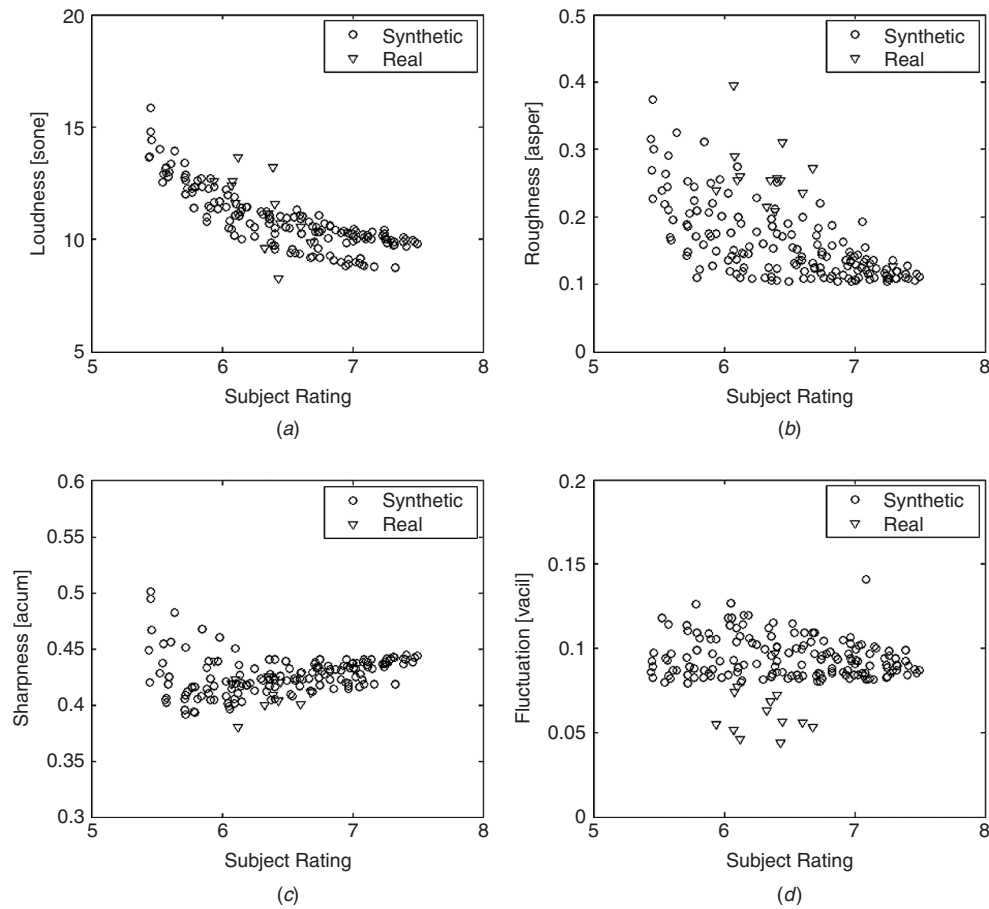

Figure 34 Sound metrics for the 170 interior sounds: (a) loudness for the signal filtered by 150 to 500 Hz frequency band filter using Zwicker's method, (b) sharpness for the 170 interior sounds of passenger cars using Bismarck's model, (c) roughness for the 170 interior sounds of passenger cars using Aures' model, and (d) fluctuation strength for the 170 interior sounds of passenger cars using Fastl's model.⁵⁴

Figure 35 (a) Correlation between the output of ANN and the averaged subjective rates for the 156 synthetic interior sounds and (b) correlation between the output of ANN and the averaged subjective rates for the 14 interior sounds of passenger cars.⁵⁴ R is the correlation coefficient.

fluctuation strength has a mean value of about 0.1 vacil, and there is no clear relationship seen between the human perception of rumbling sounds and the fluctuation strength.

Lee used the loudness and the principal rumble component of the 156 synthetic sounds to train a multiple layer artificial neural network (ANN).⁵⁴ The estimated subjective rates from the ANN are compared with subjective rankings in Fig. 35a. Figure 35a shows the correlation between the output of the ANN and the averaged subjective rates for the 156 synthetic interior sounds. Their correlation is 91.8%. Figure 35b shows the correlation between the output of ANN for the estimated rates and the averaged subjective rates for the 14 interior sounds of passenger cars. The correlation was found to be 89.2%.

The result of this research suggests that a rumbling sound index, such as the one suggested by Lee, can be devised to evaluate the subjective ranking of the rumbling sound quality of automobiles without the use of human subjects.⁵⁴

The sound quality of different commercial products obviously cannot be evaluated with the same sound quality index. The rumbling index devised by Lee should not be used, for example, with a dentist drill or hair dryer. For such cases the annoyance estimator (PA) proposed by Fastl based on loudness, sharpness, and fluctuating strength would be more appropriate.⁵⁴

PART VII

INDUSTRIAL AND MACHINE ELEMENT NOISE AND VIBRATION SOURCES – PREDICTION AND CONTROL

CHAPTER 68

MACHINERY NOISE AND VIBRATION SOURCES

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Many different machine components are used in appliances, vehicles, aircraft, and industry. Some machine components including bearings, gears, fans, burners, cutters, and valves are used in machines built from several of these components such as pumps, compressors, electric motors, and internal combustion (IC) engines. It is impossible to discuss every type of machine and machine component here; so the discussion is mainly concentrated on common machine components and machines. These machine components and machines do work, transfer energy, or convert one form of energy into another. In these processes some undesirable vibration and acoustical energy or noise is produced as an unwanted by-product. It is the purpose of this chapter to review briefly the functioning of these machine components and machines, noise and vibration generation mechanisms, and methods of control. In addition, this chapter also serves as an introduction to the chapters in Part VII of this book in which the noise and vibration of these machine components and machines are discussed in much more detail. Several other books, book chapters, and articles also discuss machinery noise mechanisms and noise and vibration sources in more detail than is possible here.¹⁻¹⁵

2 GEARS

Chapter 69 provides a detailed discussion of the sources of noise and vibration in the main types

of gears in common use. Chapter 88 also contains some information on the noise of gearboxes and transmissions used in vehicles. Most modern gear teeth have an involute profile, although some have circular-arc profiles.^{1,2} Figure 1a shows some of the terms used with involute gears and Fig. 1b shows two parallel-axis spur-type gears meshing together.

There are several different types of gears in common use, as shown in Fig. 2. They are of two main classes, either having (1) parallel axes (spur, helical) or (2) nonparallel axes (straight bevel, spiral bevel, hypoid). Spur gears and straight bevel gears are usually the noisiest, while helical spiral bevel gears are usually the quietest in their respective classes. This is because the load between gear wheel teeth is transferred more gradually with helical and spiral-bevel gears and rather more abruptly with spur and straight-bevel gears. Gear noise can arise from a variety of causes. As the gear teeth mesh, a pulsating force occurs at the gear tooth meshing frequency f_m and its harmonics. Harmonics are present because the pulsating force on the gear teeth is not purely sinusoidal. The strength of the harmonics depends on the force pulse shape and also on other impulsive forces caused by tooth deformation, production machinery errors, bearing misalignment, pinion wheel deformation, and so on. At high speeds, air or lubricating fluids can be expelled from between the meshing teeth at supersonic speeds and can even become the dominant source of noise. At low speed and load the sound pressure level produced by a gear increases by about 3 dB for a doubling of load, while

Figure 1 Terms used with gears: (a) involute gear, (b) meshing of two parallel-axis spur gears. (Based in part on figures in Refs. 1, 2, and 3.)

Figure 2 The main types of gear in use: (a) parallel axis (straight spur, helical, herringbone, rack and pinion, and planetary); (b) nonparallel axis (straight bevel, spiral bevel, hypoid, and worm.)

at higher speeds and loads the sound pressure level increases by about 6 dB for a doubling of speed or load.¹⁶

The noise of a gear set is quite dependent on the quality of manufacture and the tolerances achieved. Theoretical and experimental studies have been made that attempt to relate gear surface deformation and profiles to noise.¹⁷⁻¹⁹ Precision gear sets can now be manufactured,²⁰ which make very low noise levels, although the cost is higher. In some cases, where low noise levels are required, it is more cost effective to choose a gear set of moderate cost and to vibration isolate the pinion and gear bearings, apply damping to the gear housing, and, if necessary, completely enclose it. With gears used to transmit only small loads (e.g., those in electric clocks), very low noise levels can be achieved by the use of soft plastic gears (which reduce the gear tooth force impulses) and by other means.²¹ Manufacturing deficiencies can result in variations in pitch and profile from tooth to tooth and eccentricity of the gear wheel, which causes increased noise and vibration.^{1-4,16} There would, however, be some noise generated even if the gears were without any imperfections. The frequency of this noise (and vibration) would only occur at the gear meshing frequency f_m and its harmonics:

$$f_m = \frac{N_p n_p}{60} \text{ Hz} \quad (1)$$

where N_p is the number of pinion teeth and n_p is the pinion speed in revolutions/minute (rpm). Noise and vibration measurements have also been used to produce a gear noise and vibration rating index in an

attempt to avoid the necessity for using a jury test for this purpose.²²

3 BEARINGS

There are two main types of bearings: (1) rolling contact and (2) sliding contact.^{6,7} Rolling contact bearings are more commonly used, but sliding contact bearings are usually quieter than rolling contact bearings, if properly manufactured, installed, and maintained. Proper lubrication is essential for both rolling and sliding contact bearings. Chapter 70 presents a detailed review of the noise of bearings.

Rolling contact bearings consist of the rolling elements contained between the *inner* and *outer raceways*. The rolling elements are normally kept from touching each other by a *cage*. The rolling elements may be spherical, cylindrical, tapered, or barrel-shaped.⁶ Figure 3 shows a bearing with spherical rolling elements. The noise made by a rolling contact bearing is normally caused by vibration from two main sources: (1) rotation of bearing elements and (2) resonances in the elements, raceways, or cage. Table 1 in Chapter 70 provides formulas for the calculation of the main harmonic frequencies signifying rolling bearing defects. Reference 3 has likewise identified discrete frequencies (and their harmonics) that are related to bearing geometry and rotational speed. The fundamental frequency is the shaft rotational frequency f_s :

$$f_s = N/60 \text{ Hz} \quad (2)$$

where N is shaft rotational speed in rpm.

The other frequencies are related to the shaft frequency f_s by factors that depend on the roller

Figure 3 Bearing with spherical rolling elements.

diameter, the pitch diameter of the bearing, the contact angle between the roller element and the raceway, and the number of rolling elements. Manufacturing imperfections and misalignment cause bearing noise. This noise can be increased further by wear.

Even a perfect bearing will make noise when loaded.² If a rolling bearing is manufactured to a higher grade of precision (smaller tolerance), then it normally becomes quieter (and more expensive). (Classes of tolerance are specified in ISO Standard 492–1986. Methods to test bearings for noise and vibration are given in ANSI/AFBMA Standard 13–1970. The (American) Military Specification MIL-B-17913D defines permissible vibration limits for bearings.)

Sliding contact bearings can be divided into three main types: (1) journal, (2) thrust, and (3) guide. Journal bearings are cylindrical in shape and allow rotation (see Fig. 4). Thrust bearings are used to prevent motion along a shaft axis, while guide bearings are normally used for motion of a part in one direction without rotation (e.g., a piston sliding in a cylinder of an internal combustion engine).

When shaft rotation occurs with a journal bearing, the shaft rides on a film of lubricant. Under some conditions, however, this film can break down, causing metal-to-metal contact and consequently wear, noise,

Figure 4 Sliding contact bearing.

and vibration. A well-known instability condition called *oil whirl* can occur causing noise at a frequency of about half of the shaft rotational speed. This is because the average speed of the lubricant film is about half of the shaft speed. Oil-whirl noise can be magnified if a shaft resonance frequency occurs near to half the shaft rotational speed. To minimize sliding bearing noise, proper attention should be paid to lubricant viscosity, pressure, alignment, and structural stiffness. Proper installation of bearings is important to achieve low vibration and noise.²³ Increased bearing noise and vibration are an indication of wear and/or misalignment, and, if correctly analyzed, these can be indicative of potential bearing failure.^{24,25} Active control of special magnetic bearings for a fan has been undertaken in an attempt to set the fan blades into vibration so that they become a secondary out-of-phase sound source to cancel the primary fan noise. Noise reductions of up to 4 dB have been reported.²⁶ Chapter 70 contains more detailed discussion on bearing noise. Further discussion can also be found in Refs. 2, 3, 6, and 7.

4 FANS AND BLOWERS

Fans and blowers are used in appliances, in buildings, in air distribution systems for heating and cooling, and in industry for a variety of purposes. Fan noise, its generation, and control are discussed in detail in Chapter 71. There are two main types of fan designs: axial and centrifugal (see Fig. 5). The first three centrifugal fan types—airfoil, backward-curved, and radial—are mostly used in industrial applications. The airfoil fan is the most efficient but it is only suitable for clean-air industrial applications because dust and other particles can adhere to the fan blades and cause malfunctioning. The forward-curved fan is usually made of lightweight low-cost materials and is generally the least efficient. The radial fan is the noisiest and least efficient, but is useful for dirty or corrosive gas flows. Axial fans have the disadvantage that the discharged air rotates, unless downstream or upstream guide vanes (stators) are installed; these fans are mainly used in low- or medium-pressure air-conditioning systems. The vaneaxial fan is the most efficient axial type and can generate high pressures. The propeller type is the least expensive of the axial type. It has the lowest efficiency and is normally limited to low-pressure, high-volumetric flow applications.

The primary purpose of a fan is to move a required volumetric flow rate of air against a given back pressure with maximum efficiency and low cost and noise. There may be additional requirements such as high resistance to abrasion, ability to transport dusty air, ease of manufacture, maintenance and repair, and noise restrictions.

Fan noise has pure-tone and broadband frequency components. See Table 1 in Chapter 71. Although the mathematical theory of fan noise is well developed, it is beyond the scope of this chapter, and physical explanations are presented instead. Each time a blade passes a point in space or a solid-body obstruction, an impulsive force fluctuation is experienced by the

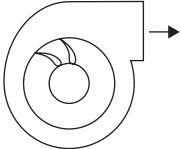

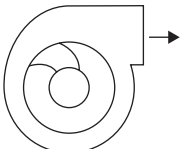

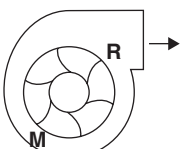

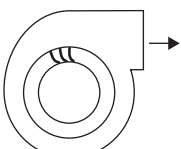

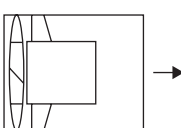

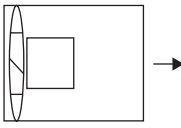

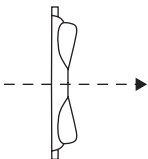

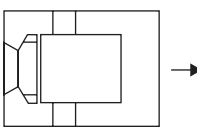

Fan Type	Description	Design Details
Centrifugal Type Fans		
Airfoil	Uses 10 to 16 airfoil shape blades; has highest efficiency of all centrifugal types; used where horsepower savings will be important; can be used on low-, medium-, and high-pressure systems.	
Backward inclined backward curved	Uses 10 to 16 blades; used for similar applications as airfoil fan; gas flow should be clean but need not be as clean as gas flow with airfoil fans.	
Industrial (radial)	Uses 6 to 10 blades of either radial (R) or modified radial (M) type; has lowest efficiency of centrifugal types; used mainly in industrial applications where gas is hot and dirty.	
Forward Curved	Uses 24 to 64 blades; construction is usually low-cost and lightweight; efficiency is lower than airfoil or backward curved fans; usually operates at lowest speed and is smallest of centrifugal types; used in low-pressure heating, ventilating, and air-conditioning (HVAC) systems.	
Vaneaxial	Uses 3 to 16 blades; high efficiency airfoil blades may be fixed or adjustable; used in low-, medium-, and high-pressure systems in HVAC and other industrial applications.	
Axial-Type Fans		
Tubeaxial	Uses 4 to 8 blades; usually more efficient than propeller type below and can operate at a higher pressure; does not use guide vanes as does vaneaxial type; used in low-, and medium-pressure systems in HVAC and other applications.	
Propeller Type	Uses 2 to 8 blades usually in a circular ring or orifice plate; efficiency low, this type usually limited to low-pressure, high volume flow applications such as exhaust or artice fans.	
Tubular Centrifugal	The fan wheel is usually similar in design to that of the airfoil or backward-curved type used in centrifugal fans since the air is discharged radially and must turn 90° in the guide vane section, its efficiency is lower than similar centrifugal fans; normally used in low-pressure HVAC return air systems.	

Figure 5 Main types of fans with descriptions of their use and design.

fluid or solid body at the point. If a fan has n blades and the rotational speed is N rpm, then the number of impulses experienced per second f_B is

$$f_B = \frac{nN}{60} \text{ Hz} \quad (3)$$

The frequency f_B is known as the *blade-passing frequency* or often the *blade frequency* for short. Since the time history of the impulsive force on the fluid or solid body obstruction at the point will not be completely sinusoidal, harmonics will appear. The strength of the harmonics is affected by upstream or downstream solid-body flow obstructions.

The noise generated by a fan depends primarily on its design features, geometrical dimensions, and operating speed and load. Both broadband and pure-tone fan noise normally increase with increasing fan speed N . The frequency of the pure-tone noise generated by a fan increases with fan speed N as shown by Eq. (3). Structural resonances can also be excited. These resonance frequencies are largely independent of fan speed. If the fan is operated at off-design conditions, its noise can also be higher than normal. If the fan is operated at reduced volumetric flow rates, the A-weighted sound pressure level can be as much as 15 dB higher than normal because of fan surge and rotating fan stall. Fan sound power level data are normally provided by manufacturers in eight octave bands from 63 to 8000 Hz. Table 2 and the associated text in Chapter 71 provide an empirical method for predicting the noise of axial and centrifugal fans.

It is difficult to reduce fan noise by changing fan design parameters since such changes may adversely affect fan performance as well. Most fan noise reduction is achieved by proper use of well-known passive control methods. If noise is of major concern and the fan has been properly installed, it will probably be necessary to install intake and discharge sound attenuators (with flexible vibration breaks at attachment points to duct systems, if present). It is also possible to provide further noise attenuation by the use of ducting, elbows, and plenum chambers lined with sound-absorbing material. Care must be taken that significant noise is not generated in this ductwork. Chapter 110 describes the prediction and control of the noise and vibration in ducted heating, ventilation, and air-conditioning systems, and Chapter 111 discusses the aerodynamic sound generated in low-speed flow ducts.

Considerable efforts continue to be made to reduce fan noise since fans are used in most computers, electric motors, household appliances, vehicles, trucks, and many other items of machinery. Numerous studies have been conducted on the noise control of fans.²⁶⁻⁴¹ Both passive²⁶⁻³⁵ and active³⁶⁻⁴⁰ noise control methods continue to be studied. Experimental and theoretical studies have been made to aid in machinery noise reduction and noise predictions. Sound quality studies have also been conducted on the acceptability of fan noise.⁴¹

5 ELECTRIC MOTORS AND ELECTRICAL EQUIPMENT

Examples of electrical equipment that cause noise and vibration include motors, generators, and alternators,^{5,13} transformers, relays, solenoids, and circuit breakers. Electric motors are used widely in appliances, vehicles, and industry in a variety of types and sizes. They may be commutated, synchronous, or induction types. Electrical energy is converted into mechanical energy, and in the process some heat is produced. Fans are often provided to remove the heat and are the main sources of noise in electric motors. Because of the requirement for most motors that they should operate in either direction of rotation, they are usually provided with axial or tubular centrifugal fans, which can be quite noisy. The sources of noise and vibration in electrical equipment are mostly aerodynamic, mechanical, and electromagnetic in nature. They are summarized in Table 1. Electric motors and the noise they generate are discussed in detail in Chapter 72.

Electric motor noise is normally controlled by passive means (use of enclosures, sound-absorbing materials, vibration isolation, etc.) The pure-tone vibration and noise produced at twice line frequency and multiples can also be reduced by active control methods, although active control of electrical equipment so far has received limited attention. One exception is the active control of the vibration and noise of large electrical transformers, which has been successfully reduced by active vibration control approaches.

6 PUMP AND PUMPING SYSTEM NOISE

Chapter 73 presents a detailed review of the noise of pumps and pumping systems. Pumps are used to transport liquids and suspensions of solid particles in hydraulic systems. The noise generated in such systems is produced not only by the pump but also by the driving motor (usually an electric motor with its cooling fan). The noise and vibration created is

Table 1 Main Sources of Noise in Electric Motors

Mechanical	Excessive bearing clearance
	Nonround bearings
	Rotor unbalance
	Rotor eccentricity

Electromagnetic	Magnetostriction
	Torque pulsations
	Air gap eccentricity
	Air gap permeance variation
	Dissymmetry
	Sparking or arcing
Aerodynamic	Fan blade-passing frequency
	Turbulence
	Noise due to airflow path restrictions

carried throughout the hydraulic system as fluid-borne noise and mechanically by the pipe system itself as structure-borne noise.^{42,43}

There are three main types of pumps: (1) positive displacement, (2) kinetic (i.e., dynamic), and (3) special effect. Some of the main pump designs are illustrated in Fig. 1 of Chapter 73 and are similar in many ways to compressors used to pump or transport gases as described in the next section of this chapter and in Chapter 74. Positive-displacement pumps work by periodically adding energy to the fluid by one or more elements moving within a cylinder or pump case. In a similar way to positive displacement compressors, positive displacement pumps can be further subdivided into reciprocating and rotary types. The operation of a pump causes mechanical forces resulting in vibration, and even more important, pressure pulsations in the fluid, both of which cause noise. Rotary pumps can be divided into two main types: those possessing single rotors and those with multiple rotor elements. There are many different types of single- and multiple-type pumps including vane, gear, lobe, and screw types as shown in Fig. 1 of Chapter 73.

The main sources of noise in reciprocating pumps include: (1) flow and pressure pulsations sometimes called “ripple,” turbulent and separated flows, and vortex formation in the fluid, and (2) unbalanced mechanical forces, inlet and discharge valve impacts, and piston slap. The main sources of noise in rotary pumps depend upon the pump design and include (1) fluid pressure pulsations, turbulence, and vortices and (2) mechanical forces resulting from impacts between the teeth of gear pumps, the sliding of the vanes of vane pumps, and friction forces created in screw types of pumps. Gear pumps are noisy since they trap and compress the working fluid between the gear teeth and expel it perpendicular to the axes of revolution. They can operate at pressures of 150 bars

or more. Screw pumps are generally much quieter and move the fluid in a direction parallel to the screw axis but are limited to lower pressures, usually less than about 40 bars.

Various designs of pump have been produced to reduce ripple.⁴³ One novel design has gear/screw elements that makes it a cross between a gear and screw pump. (See Fig. 6.) The two contrarotating elements tend to balance internal forces and torques thus reducing vibration and noise. It is claimed that this type of pump, termed a Continuum[®] pump, virtually eliminates the trapping of fluid between gear teeth by using special helical gears, which results in much less pressure ripple and pump noise. The pump can operate at speeds up to 5000 rpm and pressures as high as 240 bars. Figure 7 shows the pressure pulsations (ripples) for two different designs of gear pump and the Continuum[®] pump when they were all operated at

Figure 6 Continuum[®] continuous-contact pumps feature helical gears that do not trap fluid as they rotate, as is the case with conventional gear pumps. This minimizes pressure ripple and gives high efficiency and quiet operation at speeds to 5000 rpm.⁴³

Figure 7 Laboratory tests that show reduced pulsation pressure (ripple) for the continuous-contact Continuum[®] pump compared with similar gear pumps. The pulsation tests were conducted at 100 bars, 1500 rpm, and with pressure sampling at 100 kHz.⁴³

Figure 8 Laboratory measurements of the noise of two external gear pumps and the Continuum[®] pump. The measurements were made when all of the pumps were running at 1500 rpm. The pressure produced by all the pumps in the noise test was 150 bars.⁴³

1500 rpm and a pressure of 100 bars. It is seen that these continuous-contact pumps exhibit a much smaller magnitude of ripple. Figure 8 presents the A-weighted sound pressure levels measured using the ISO 4412 method for two gear pumps and the continuous-contact pump when they were tested under similar operating conditions. The overall A-weighted sound pressure level of the continuous-contact pump does appear to be of the order of 5 to 8 dB lower than the noise levels of the two other pumps and supports the idea that the pressure ripple is a major source of noise in most pump types.

The flow and pressure ripple effects can also be reduced by the use of dampers or accumulators and/or by very careful and precise manufacturing and grinding of the parts of the pump. Dampers can be similar to muffler expansion chambers in design or have special design features including flexible membrane parts to absorb the pressure pulsations. Efforts continue to be made to reduce pump ripple⁴⁴ and cavitation,^{45,46} which can cause serious damage to pumps and hydraulic systems. Different methods are used to improve pump design⁴⁷⁻⁴⁹ and also for diagnostics and health maintenance of pumps and hydraulic systems.^{50,51} Precision grinding of parts does add cost and this must be considered in choosing a pump system.

7 COMPRESSOR NOISE

Compressors can be considered to be pumps for gases. Although there are some differences in construction details between compressors and pumps, their principles of operation, however, are essentially the same. (See Chapter 74.) Since gases normally have much lower densities than liquids, it is possible to operate compressors at much higher speeds than pumps. However, gases have lower viscosities than most liquids

and so leakage with compressors is more of a problem than with pumps. Thus, this requires tighter manufacturing tolerances in the moving parts of compressors. Due to the low viscosity of gases and their compression, the temperature of the working medium and of the machine itself increases during compression. As a consequence, when the pressure ratio from after to before compression is more than about five, additional cooling is needed for the compressor and lubrication system. This makes compressors more complicated, as regards maintenance and servicing than pumps used for liquids. In general compressors are more expensive to operate than pumps.

Compressors are used for many different applications, and there are a large number of quite different designs. Rather like pumps, there are two basic types of compressor: (1) positive-displacement compressors including reciprocating piston, and rotary types and (2) dynamic compressors including axial and centrifugal types. Like pumps, there are a few special-effect compressor types as well. Positive-displacement compressors operate by increasing the pressure of the gas by reducing its volume in a compression chamber through work applied to the compressor mechanism. Dynamic compressors, on the other hand, work on the principle of using bladed impellers on continuously flowing gas to increase its kinetic energy, which is eventually converted into potential energy and gas of higher pressure.

Very large numbers of small positive-displacement compressors have been mass produced around the world for use in household refrigerators and domestic and automobile air-conditioning systems. Considerable efforts, which are driven in part by market forces, have been expended to produce quieter small positive-displacement compressors. Positive-displacement compressors can be characterized by the location of the motor: (1) External-drive (open-type) compressors have a shaft or other moving part extending through the casing and are driven by an external power source, thus requiring a shaft seal or equivalent rubbing contact between fixed and moving parts; (2) hermetic compressors have the compressor and motor enclosed in the same housing shell without an external shaft or shaft seal and the motor operates in the compressed gas; and (3) semi-hermetic refrigerant compressors have the compressor directly coupled to an electric motor and contained within a gas-tight bolted casing. Positive-displacement compressor mechanisms can be further subdivided into (a) reciprocating types: piston, diaphragm, or membrane, and (b) rotary types: rolling piston, rotary vane, single-screw, twin-screw, scroll and, trochoidal (lobe).

The noise generated by the piston type of compressor depends upon several factors, the most important being the reciprocating frequency and integer multiples, number of pistons, valve dynamics, and acoustical and structural resonances. The noise produced by the rotary types depends upon rotational frequency and multiples, numbers of rotating elements, flow capacity, and other flow factors. The

noise generated by centrifugal and axial compressors also depends upon rotational frequency, that is, the number of rotating compressor blade elements. Flow speed and volume flow rate, however, are also important factors. Such dynamic compressors are used in aircraft jet engines and large commercial electricity generating plants. Chapter 74 describes some design, operational noise, and vibration features of several categories of dynamic compressors in use and also gives some examples of how noise and vibration problems have been overcome in practice.

8 CONTROL VALVES

Control valves are used in industrial plants to control the rate of fluid flow by creating a pressure drop across the valve. The flow is first accelerated by this process and then the kinetic energy is converted into thermal energy or heat through turbulence and/or shock waves. In the process a small fraction of the energy is converted into acoustical energy and thus noise. The aerodynamic noise generated by control valves, regulators, and orifices is a major noise source in piping systems. In some cases exterior noise levels as high as 130 dB can be produced. In addition, in liquid flow systems, hydrodynamic noise (which is mostly due to cavitation) is of some importance. However, in most industrial situations, with high-speed gas flows, the aerodynamic noise is dominant.⁵² The main noise-generating mechanisms include turbulent mixing, turbulence interaction with boundaries, cavitation in liquids, shock waves, interaction of turbulence with shocks, cavity resonances, flow separation, vortex shedding, "whistling," and resonant mechanical vibration of valve components.^{53,54} Figure 9 presents a simplified view of a control valve and some of the noise sources.⁵⁴ See Chapter 75 for an extensive discussion on this subject. Comprehensive reviews of control valve noise have also been given by Reethof.^{53,54} Seebold has reviewed control valve noise sources and approaches for noise control.⁵⁵

The major noise-generating processes can be divided into two regimes: *subsonic*, consisting mostly

of turbulence–boundary interaction noise, and *supersonic*, consisting mainly of broadband shock noise. Although the flow is confined by the piping, the turbulent mixing noise is similar to the noise of a free jet discussed in Chapters 9 and 89 and is essentially quadrupole in nature. The shocks are caused by abruptly expanded flow after the valve, when it is operating above the critical pressure ratio. The shock noise has two main parts: screech and broadband noise. The screech is discrete in nature and is caused by a feedback mechanism and is not often encountered with valves and regulators. The broadband shock noise is common, however, and has been shown to be mostly independent of flow velocity and to be a function of the pressure ratio across the valve. Valve noise can be reduced by several approaches including design of valves with multiple streams, arranging for the pressure drop to occur through several stages, and using absorptive silencers, thicker pipe walls, and pipe lagging. Multiple stream valve designs and absorptive silencers are effective at reducing noise. Absorptive silencers can produce noise reductions of as much as 15 to 30 dB. However, such silencers can become plugged by solid particles and moisture can be a problem in the silencer material so that effectiveness is lost. Chapter 75 deals in detail with noise-generating mechanisms and the prediction and control of control valve noise. Several other authors have also given helpful reviews of valve and piping system noise, and the reader is referred to these as well for more detailed discussions.^{15,52–55}

9 HYDRAULIC SYSTEM NOISE

Chapter 76 deals with high-pressure hydraulic fluid power systems using positive-displacement pumps. The diameter of pipes used in such systems is usually quite small (of the order of 10 to 50 mm). The flow is normally single phase with negligible gas bubble and solid particle content. The usual operating pressures are of the order of 100 to 300 bars. There are systems, however, which operate at pressures of up to 500 or even 650 bars. Hydraulic systems often produce very high noise levels that can limit the range of

Figure 9 Schematic representation of control valve noise generation and propagation.⁵⁴

applications of fluid power systems. Potential high-level noise problems can result in the choice of an alternative means of power transmission in cases where low-noise systems are required.

As discussed in Chapter 76, hydraulic system noise sources may be categorized as follows: (1) *Airborne noise* originates from the vibration of components, piping, and housings and is transmitted directly through the air. (2) *Structure-borne noise* is caused by the mechanical operation of pumps and motors and is transmitted from pumps directly through mounts, drive shafts, and pipes. Structure-borne noise can also arise from the pressure “ripple” in the hydraulic system. (3) *Fluid-borne noise* is caused primarily by unsteady flow from the pumps and motors but can also be caused by valve instability, cavitation, and/or turbulence. Fluid-borne noise can be transmitted considerable distances through pipework with little attenuation. Figure 10 gives an illustration of (a) structure-borne noise and (b) fluid-borne noise (commonly called ripples) created by a multipiston axial-flow pump.

The main sources of noise in a hydraulic system are usually the pumps and motors. Valves are also important noise generators. See Chapter 75 for further discussion on valve noise. Positive-displacement pumps are mainly used in fluid power applications. The most common types are piston pumps, gear pumps, and vane pumps. See Chapter 73 for more detailed discussion on pump noise. Positive-displacement pumps produce a steady fluid flow rate on which is superimposed

a flow fluctuation or ripple, which is caused by the cyclic nature of the pump operation. The flow ripple is also manifested as a pressure fluctuation or ripple. The magnitude of the flow ripple depends on the pump type and its operating conditions. See Chapter 76. Flow ripple normally occurs in both the suction and the discharge lines. Usually the discharge flow ripple is the most important noise source. Fluid-borne noise in the suction line may cause noise problems especially when it causes vibration and noise radiation from a large-surface reservoir.

There are several ways of reducing the noise of hydraulic systems as described in Chapter 76 and Ref. 9. These include (1) reduction of the pump or motor flow ripples,⁴³ (2) tuning of the circuit in order to avoid resonant conditions, (3) use of silencers or pulsation dampers, (4) using flexible hoses,⁴² (5) vibration isolation,⁴² and (6) use of enclosures or pipe cladding.

10 COMBUSTION NOISE

As described in Chapter 77, the phenomenon of thermoacoustically induced oscillations and combustion noise, or “roar,” in combustion systems is complicated and usually only qualitative explanations can be given. Various empirical methods have been developed to predict combustion noise. In practice, engineering solutions are mainly used to control combustion oscillations and noise.

Combustion systems consist of two main fuel and air delivery system components: (1) burner and

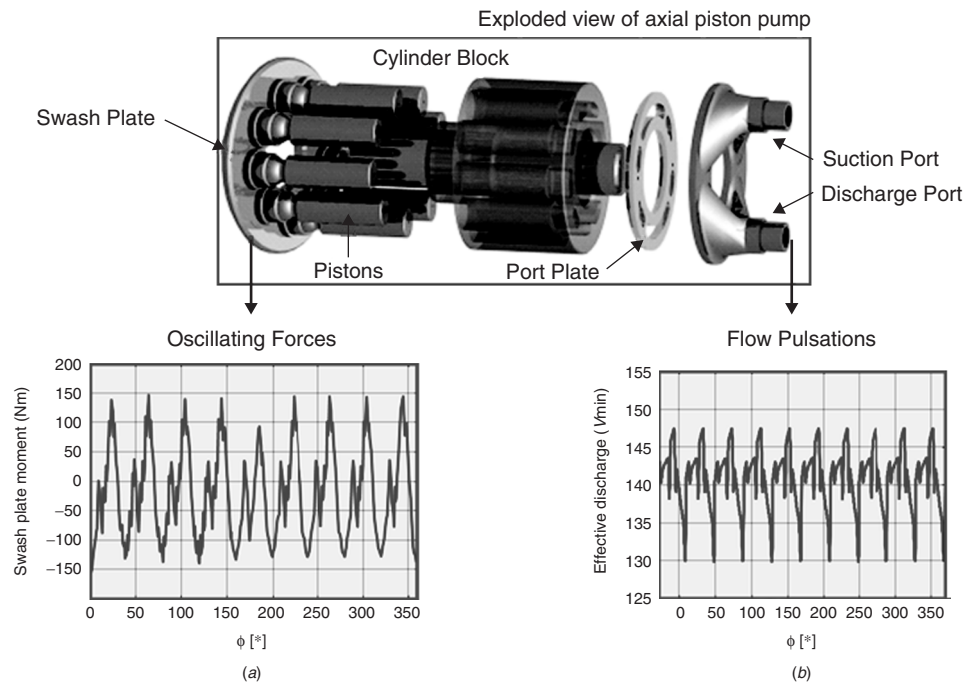

Figure 10 Pump forces result as airborne noise (not shown) and (a) structure-borne noise through the piping system and (b) fluid-borne noise (flow and pressure fluctuations called ripples).

(2) combustor. The fuel injection component is usually called the burner. The element within which the heat release takes place is normally referred to as the combustor or furnace. The purpose of combustion systems is to add heat to an airstream. The main mechanisms that produce combustion noise are common to all combustion systems.

As described in Chapter 77, the purpose of the fuel burner is to mix and direct the flow of fuel and air to ensure rapid ignition and complete combustion within the furnace or combustor. The combustion of gaseous fuels takes place mainly in two ways: (1) when the gas and air are mixed before ignition, known as premix flames, and (2) when the gas and air are mixed after the fuel has been heated, known as diffusion flames.

The noise generated by the combustion can be considered to be either (1) combustion roar or (2) combustion-driven oscillations or thermoacoustic instabilities. The latter type of noise is observed when pressure oscillations are induced by heat release oscillations. Although thermoacoustic instabilities are closely related to flame instabilities, their instability criteria are different. The main focus of Chapter 77 is on thermoacoustic instabilities since they can produce higher sound pressure levels than combustion roar and since they also have a greater potential for structural damage. It should be noted that some researchers further subdivide combustion noise into four categories.^{56,57} Figure 11 shows two types of flame. Type 1 flames tend to be relatively quiet and type 2 flames tend to be relatively noisy. It has been found by several researchers that if sufficient swirl is introduced into the flow that flames change from type 1 to type 2.⁵⁶⁻⁵⁹

There are two main passive noise control measures available: (1) reducing the combustion-induced sources and (2) use of traditional noise control approaches including use of absorptive mufflers,

acoustical resonators, enclosures for the burner, furnace, or boiler or other units to which they are attached. Active approaches to control thermoacoustic oscillations have also been attempted as described in Chapter 77.

11 METAL CUTTING

Many industrial processes involve cutting metals. Metal-cutting processes can either be *continuous* or *impulsive* in character. Examples of continuous processes include sawing, drilling, milling, and grinding. Additional continuous cutting processes use of water jets, for cutting steel plates up to 300-mm thickness and plasma and laser cutting techniques. Examples of impulsive processes include punching, piercing, and shearing. Chapter 78 discusses noise sources due to *continuous* metal-cutting processes and to *impulsive* impact/shearing processes. The chapter also covers basic theory for the noise emission caused in the cutting of metals. In addition various noise control approaches (such as use of enclosures, damping materials, sound absorption materials, barriers, and vibration isolation) to reduce metal-cutting noise are presented. Chapter 78 reviews numerical methods to predict metal-cutting noise and vibration as well.

As described in Chapter 78 the following noise sources can be observed in continuous metal-cutting processes: (1) aerodynamic noise usually caused by vortex shedding from a spinning tool such as from the teeth of a high-speed rotating saw, (2) noise caused by vibrations of the cutting tool, (3) noise due to structural vibration and radiation from the cutting tool and the workpiece such as regenerative chatter, and (4) noise due to material fracture in which energy is built up until it is released at fracture as acoustic emission.

The noise level radiated by continuous cutting processes depends on the feed rate of the workpiece,

Figure 11 Flame types in burners incorporating swirl.⁵⁷

the depth of cut, the resonance frequencies of the cutting tool and the workpiece, the geometry of the cutting tool and the workpiece, and the radiation efficiencies of the resonant modes of vibration. In impulsive cutting processes such as stamping, forging, punching, piercing, and shearing, impulsive forces are involved. The noise generated by these operations includes acceleration noise, ringing noise, noise due to fracture of the feedstock material (cutting noise), and other machinery noise sources. Acceleration noise is generated by the impact between the cutting blade and the feedstock, causing the air around to be compressed due to the rapid surface deformations. This noise is usually low frequency in nature and is normally much less than the ringing noise caused by flexural vibrations.

Ringing noise is generated from vibrations of the feedstock and machine structure including the machine foundations; it usually makes a significant contribution to the overall noise generated during the metal-cutting process. The magnitude of the ringing noise depends on the radiation efficiency, and spatial averaged mean-square normal vibration velocity of the surface and its area, the air density, and speed of sound in air. In some cases, the ringing noise can be effectively reduced by the judicious use of damping materials. Richards et al. have published extensive discussions on acceleration noise and ringing noise.^{60,61} Chapter 78 also provides more details. Ringing noise can be reduced by mechanical clamping of the workpiece as shown, for example in Fig. 12. The blade-radiated noise is also reduced because the saw blade is “buried” beneath the work table for much of the time, and the operator is shielded from its noise. Acoustical shielding such as this is particularly effective for the high-frequency saw blade noise.

Large numbers of circular saws are used all over the world to cut metal, stone, and wood. They are an effective but very noisy form of cutting tool. Many different passive methods have been used to reduce the noise of circular saws. These range from source, path, to receiver approaches. The most effective approach is to control the saw noise at the source. One approach reported by Bobeczko involves minimizing the kerf (tooth width), slotting the blade body and adding collars to stiffen and damp the blade vibration, see Figs. 13 and 14.⁶² Figure 14 shows that an A-weighted noise reduction of 19 dB was achieved in this particular case. This particular type of blade was used extensively over seven years without mechanical problems.⁶² To avoid problems, however, it should be made by a skilled machinist.⁶²

It is believed that the blade shown in Fig. 13 is substantially quieter than similar blades, because (1) the natural modes of vibration have been changed, (2) the slots allow some cancellation of sound radiated from the front and back of the blade, and (3) the added collars and plugged stress release holes add some stiffness and damping, thus reducing the blade vibration and consequent sound radiation. Research continues on reducing metal cutting noise.^{63–70}

Figure 12 Saw blade noise control.⁶²

12 WOODWORKING NOISE

Woodworking machinery includes a wide variety of equipment, ranging from off-road forest equipment to simple circular saws, band saws, and jig saws used in industrial and residential workshops. Extremely high noise levels produced by these woodworking machines during both operating and machine idle conditions pose a severe threat to the hearing of the operators of such machinery. See Chapter 79.

Many industrial woodworking machinery noise sources result from the use of cutters and saw blades. Cutters are widely used in the woodworking industry on machines such as planers, molders, cutters, routers, and the like to smooth and shape wood. Most cutters have several rows of knives that protrude above the cutter body, which is normally cylindrical. In many cases the machining process involves a peripheral milling in which each knife removes a “chip,” leaving a relatively smooth surface. The smoothness of the cut depends on the machine feeds and speeds used. Most cutters have straight knives (aligned parallel to

Figure 13 Slotted saw blade.⁶²

Figure 14 Octave band noise levels of saw blades. Overall A-weighted levels also shown 109 dB — conventional blade, 90 dB — slotted blade.⁶²

Figure 15 (a) Use of complete panel enclosure for molder noise and (b) use of mass-loaded vinyl "curtains" to control rip saw noise.⁷¹

the cutter rotational axis). This design of cutter is used because it is easy to manufacture and sharpen as needed. Although this design of cutter is effective in working the wood, it is inherently noisy.

The compression of the air, which is caused when cutters rotate near to a stationary surface, results in a siren-type noise mechanism. This mechanism is very efficient in generating sound. This noise is pure tone in nature and occurs at the knife blade passage frequency. As discussed in Chapter 79, the rotating cutter A-weighted noise level increases with cutter rpm and also increases with decreasing distance (clearance) between the knives and the stationary surfaces. The A-weighted noise level produced by rotating cutters during idle also increases with increasing length of the cutter.

Complete durable panel enclosures such as those illustrated in Fig. 15a can have an A-weighted insertion loss of as much as 20 dB, provided considerable care is taken to seal the enclosure wherever it is possible and feasible. The enclosure shown in Fig. 15a was built to house a wood molder and is provided with a viewing window and an entry door to provide access to the tool inside. An additional barrier/guard at the wood output location is provided to accommodate varying sizes of wood parts being molded.⁷¹ The insertion loss is limited in practice by the need for the penetration provided for the workpiece. Figure 20 in Chapter 54 shows another similar example of a woodworking machine enclosure for a band saw. The A-weighted insertion loss of mass-loaded vinyl barrier quilted blankets (commonly called "curtains"), as shown in Fig. 15b, is typically only about 5 to 7 dB. However, the assembly of the curtain system is relatively simple and the cost of the mass-loaded curtain system shown in Fig. 15b, is less than that of the complete enclosure shown in Fig. 15a. Curtains, however, are not as durable as panel enclosures and normally must be replaced periodically.

13 NOISE CONTROL OF INDUSTRIAL PRODUCTION MACHINERY

Chapter 80 discusses noise in production areas of manufacturing plants. Production machinery and equipment that generate intense noise include machines that operate with impacts such as forging hammers,^{72,73} cold headers, stamping presses, riveters, jolting tables, some machine tools, and impact-generating assembly stations. With the exception of forging plants, in which forging hammers are the dominating source of noise, noise sources in manufacturing plants can be typically classified in order of intensity/annoyance as: (1) *compressed air* (leakages, air exhaust, air blowing nozzles), (2) *in-plant material handling systems*, and (3) *production and auxiliary machinery and equipment*. The two basic noise reduction techniques are (1) use of acoustical enclosures, which are expensive to build and maintain, may reduce efficiency of the enclosed equipment, and are not always feasible, and (2) noise reduction at the source, which is effective but often requires a research and development effort. Chapter 55 describes different methods of identifying sources of noise and vibration in machinery.

Chapters 54 and 56 to 62 describe the main methods of passive noise and vibration control. Chapters 63 and 64 describe methods of active noise and vibration control and Chapter 66 discusses ideas of how machines can be designed to be quiet, right from the inception. Reference 74 contains a large number of case histories of successful noise reduction projects carried out in industry.

14 MACHINE TOOL NOISE, VIBRATION, AND CHATTER

Chapter 81 discusses the problem in the manufacturing industry of the chatter-induced vibration in machine tools during machining. Such problems occur, for example, in turning, milling, boring, and grinding. Chatter is very undesirable. Not only does it create noise but the vibration that it produces also results in an uneven cut and undesirable cut quality. The vibration of machine tools may be divided into three different classes: (1) free or transient vibrations of machine tools excited by other machines or engagement of the cutting tool and the like, (2) forced vibrations usually associated with periodic forces within the machine tool, for example, unbalanced rotating masses, and (3) self-excited chatter that may be explained by a number of mechanisms. These mechanisms include, among others, the regenerative effect, the mode coupling effect, the random excitation of the natural frequencies of the machine tool caused by the plastic deformation of the workpiece material, and/or friction between the tool and the cut material. Vibration in machine tools affects the quality of machining, particularly the surface finish. Furthermore, machine tool life can be correlated with the vibration and noise levels produced. Machine tool chatter may be reduced by selective passive or active modification of the dynamic stiffness of the tooling structure and/or by the control of cutting data and its use to maintain stable cutting. Forced unbalance vibration in rotating tooling structures may be reduced by passive balancing or active online balancing.

The vibration of machine tools may be divided into three different classes: free or transient vibration, forced vibration, and self-excited chatter or vibration. Free or transient vibrations of machine tools may be excited by other machines in its environment via the machine tool base or/and by rapid movements of machine tables, engagement of the cutting tool, and the like. The forced vibrations are usually associated with periodic forces within the machine tool, for example, unbalanced rotating masses, or the intermittent tooth pass frequency excitation in milling. This type of vibration may also be excited by other machines in the environment of the machine tool via its base.

Machine tool vibrations during machining operations are usually denoted *self-excited chatter* or *tool vibration*. Depending on the driving force of tool vibration, the vibration is generally divided into one of two categories: regenerative chatter (secondary chatter) and nonregenerative chatter (primary chatter). See Refs. 75 to 77 for examples. Extensive research has been carried out on the mechanisms that control the induction

of vibrations in the cutting process. The majority of this research has involved the dynamic modeling of cutting dynamics focusing on analytical or numerical models. Usually, the purpose of this work is to produce dynamic models for the prediction of cutting data that ensure stable cutting and maximize the material removal rate. Active control has also been investigated for turning and boring operations.^{78,79}

15 SOUND POWER LEVEL PREDICTIONS FOR INDUSTRIAL MACHINERY

Chapter 82 discusses procedures for calculating the sound power level of industrial machinery. In the European Community (EEC) it is required to determine the sound power level of some items of machinery and to provide a label on the machine giving this information. The measured or calculated sound power levels (given in Chapter 82) can be used for predicting the sound pressure levels in a space or developing purchase specifications for new equipment.

With any project, acoustical data measured and calculated in accordance with recognized standards should be obtained. Many manufacturers provide sound power levels or measured sound pressure levels at 1 m from their equipment, and some offer special low-noise options. If manufacturer's data are unavailable, efforts should be made to measure a similar unit in operation. If this is not practical, then the material in Chapter 82 can be used.

Most of the equations presented in this chapter are based on measured data and tend to be conservative, usually predicting somewhat higher sound pressure levels than are measured in the field. Due to recent efforts at reducing equipment noise, sound pressure levels for some equipment may be significantly (10 dB) quieter than the levels calculated in this chapter.

Some equipment consists of several different sound-producing components such as motors, pumps, blowers, and the like. The sound power levels for each component should be determined and then combined (using correct decibel addition) to get the total sound power levels.

16 INTERNAL COMBUSTION ENGINES

The internal combustion engine is a major source of noise in transportation and industrial use. The intake and exhaust noise can be effectively silenced. However, the noise radiated by engine surfaces is more difficult to control. In gasoline engines, a fuel-air mixture is compressed to about one-eighth to one-tenth of its original volume and ignited by a spark plug. In diesel engines air is compressed to about one-sixteenth to one-twentieth of its original volume and liquid fuel is injected in the form of a spray; then spontaneous ignition and combustion occurs. Because the rate of pressure rise is initially more abrupt with a diesel engine than with a gasoline engine, diesel engines tend to be noisier than gasoline engines. The noise of diesel engines has consequently received more attention from both manufacturers and researchers. The

noise of internal combustion engines is discussed in detail in Chapter 84.

The noise of engines can be divided into two main parts: combustion noise and mechanical noise. The combustion noise is caused mostly by the rapid pressure rise caused by ignition, and the mechanical noise is caused by a number of mechanisms, with perhaps piston slap being one of the most important, particularly in diesel engines. The noise radiated from the engine structure has been found to be almost independent of load, although dependent on cylinder volume and even more dependent on engine speed.⁸⁰ Priede has given a good review of internal combustion engine noise with an emphasis on diesel engine noise.⁸¹ Reference 14 also includes detailed discussion on various aspects of engine noise.

CHAPTER 69

GEAR NOISE AND VIBRATION PREDICTION AND CONTROL METHODS

Donald R. Houser

Gear Dynamics and Gear Noise Research Laboratory
The Ohio State University
Columbus, Ohio

1 INTRODUCTION

Gears are used in numerous applications where mechanical power is transmitted. If even an infinitesimal fraction of the transmitted power is converted to noise, gears can emit annoying and sometimes harmful sounds. The noise of gears in automobiles and other consumer products such as appliances, printers, and toys may be objectionable to the listener. The gear noise may actually exceed legal requirements and/or cause hearing damage in higher power products such as aircraft, ships, and industrial machines.

Two types of gear noise exist: whine and rattle. Gear whine is a periodic sound characterized by tones at the gear mesh frequency and its harmonics (integer multiples of mesh frequency). Gear rattle is an impulsive sound that occurs in lightly loaded gears that are externally excited by an oscillating torque. In practice, gear whine is usually more important than gear rattle, but gear rattle is sometimes of concern. The analysis of gear noise and its predominant frequencies are of considerable importance in the understanding of the gear vibration and noise generation process.

2 VIBRATION AND NOISE ENERGY FLOW

Figure 1 shows a typical gear arrangement of a modestly complex gearbox in which both displacement and force excitations occur at each gear mesh. The forces created at the mesh then excite the gear blanks and support shafting, both in the torsional and lateral directions. The resulting shaft dynamics then cause forces to be transmitted through the bearings to the housing, with the housing's vibrating panels radiating noise to the surroundings. Dynamic forces might also be transmitted either through the housing mounts or along the connecting shafts to other noise radiating surfaces. Figure 2 shows the energy flow in schematic form. This figure may be used by analysts to identify the steps in developing models to predict noise and vibration and by experimentalists to identify transducer locations along the gear noise and vibration paths.

3 GEAR NOISE AND VIBRATION IDENTIFICATION – THE FREQUENCY SPECTRUM

Gear whine is characterized by a periodic sound that has major components at the gear mesh frequency and

Figure 1 Multimesh gear train schematic.

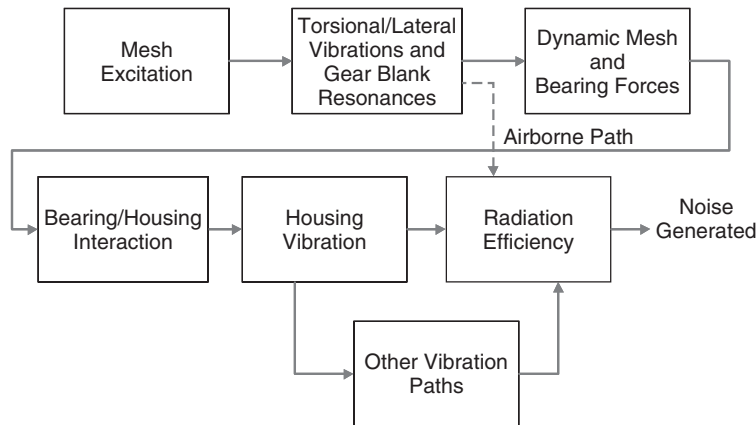

Figure 2 Gear noise energy flow diagram.

its harmonics. The mesh frequency may be calculated using the equation:

$$f_m = Nf_s$$

where N is the number of gear teeth and f_s is shaft frequency in hertz. A 25-tooth gear rotating at 1200 rpm has a mesh frequency of $f_m = 25 \times 1200/60 = 500$ Hz. The mesh frequency computation for planetary gears is a bit more complex and depends upon the gear configuration.

The excitation of gear whine noise is periodic but is seldom sinusoidal. Therefore, gear whine noise will also occur at harmonics of mesh frequency. Modulations due to tooth spacing errors, eccentricities, and torsional vibrations may create sidebands that are spaced at shaft frequency intervals on either side of mesh frequency and its harmonics. These frequencies are identified on the frequency spectrum of Fig. 3.

Gear rattle, on the other hand, is difficult to identify from a frequency spectrum. The repeated impacts that occur from the loss of gear contact only increase

broadband noise that shows up as a rising of the noise floor of the spectrum.

4 GEAR WHINE EXCITATION

A survey of the literature has identified the following quantities that have been identified as excitations of gear whine noise¹:

1. *Transmission Error (TE)* Defined as the deviation from perfect motion transfer of gears. Transmission error may be attributed either to profile deviations from perfect involutes (conjugate shapes) or to gear deflections that result from the transmitted load. The equation for angular transmission error, when referenced to the pinion, is

$$TE = \theta_p - m_g \theta_g$$

where θ_p and θ_g are the angular rotations of the pinion and gear, respectively, and m_g is the gear ratio. Transmission error may be expressed in linear units by multiplying the angular value by the pinion base radius.²⁻⁴

2. *Mesh Stiffness Variation* The change in tooth stiffness that occurs when the lengths of lines of contact change as the number of tooth pairs in contact change. These stiffness variations result in a time-varying parametric excitation of the torsional dynamic system. The deflection portion of transmission error results from mesh stiffness changes.⁵
3. *Axial Shuttling Force* A time-varying force at the bearings due to the centroid of the mesh force axially shifting back and forth along the tooth face width.⁶
4. *Friction Force* Results from the relative sliding that occurs in gear tooth meshing. As with axial shuttling, statics may be applied

Figure 3 Frequency spectrum for a gear pair having a 25-tooth pinion rotating at 1200 rpm.

to obtain time-varying bearing forces resulting from friction.^{6,7}

5. *Lubricant and/or Air Entrapment* In high-speed gearing, the air and lubricant in the root clearance and backlash regions must find an exit path. This may result in high velocities of pulsating fluid motion that can result in mesh frequency whistles.

Transmission error and mesh stiffness variation are closely related to one another and have historically been considered the primary gear noise excitations.^{5,8-11} At light loads, transmission error is definitely the major cause of gear whine. However, at higher loads, low transmission error gears often still have significant gear noise, thus giving credence to load-dependent sources such as friction and shuttling. Since gear noise is generated from forces passing through the bearings and then exciting the housing, a more general gear excitation would be to calculate the net time-varying force that excites the bearings.¹²

4.1 Gear Geometry Used in Predicting Gear Noise Excitations

Parallel axis, involute spur gearing will be discussed in this section, but the concepts presented may be extended to all types of gearing. The involute tooth shape is by far the most common tooth form in use today. The involute form is generated by unwrapping a string from the base circle (radii r_b and R_b , respectively) of each gear. In involute gears, the tooth contact force acts on a line tangent to the respective base circles of each gear as shown in Figure 4. Fig. 5 shows an expanded view of the line of contact in relation to a tooth of one of the mating pair. Here, Z is the length of the line of contact, which, for the driving gear tooth, begins at the start of the active profile (SAP) and extends to the tip of the tooth. As the gears rotate, the meshing begins with two pairs of teeth in contact and transitions to a single-tooth pair in contact in the central region of the tooth. Both the lowest point of single-tooth contact (LPSTC) and the highest point of single tooth contact (HPSTC) are designated on the figure. Contact ratio, the average number of tooth pairs in contact, is the ratio of the total length of contact, Z , to the base pitch, p_b (spacing of teeth along the base circle). The length of the contact may be calculated by

$$Z = \sqrt{r_o^2 - (r_p \cos \Phi)^2} + \sqrt{R_o^2 - (R_p \cos \Phi)^2} - C \sin \Phi$$

where r_o and R_o are the outside radii and r_p and R_p are the operating pitch radii of the respective gears, C is the center distance, and Φ is the pressure angle.¹³ A contact ratio of 1.4 means that two pairs of teeth are in contact 40% of the time and that one pair of teeth are in contact 60% of the time. When two tooth pairs are in contact, the mesh stiffness is about twice that of when one pair of teeth is in contact.

Figure 6 shows, for a perfect involute gear pair, the effect of stiffness change on the transmission error, first

Figure 4 Gear contact line and the geometry associated with computing the contact ratio of a gear pair.

Figure 5 Line of contact nomenclature (numbers along the line indicate number of tooth pairs in contact).

Figure 6 Transmission error and stiffness change for a perfect involute spur gear pair.

when the gears are under no load and then when they are fully loaded. Note that the gears run ideally with zero transmission error at no load. When the gears are loaded, the mesh deflection, which is a measure of transmission error, changes in a stepwise fashion as the number of tooth pairs in contact changes from one to two. A 3-module, fully loaded gear pair would have a deflection value in the order of 25 μm , so a

typical transmission error in this situation would have a peak-to-peak value of 12.5 μm . Also shown in this figure is the force carried by a single tooth as it rotates through the mesh. The step changes in tooth force are undesirable from a dynamics perspective.

4.2 Minimizing Transmission Error – Effect of Profile Modifications

Transmission error in spur gears is minimized by removing material from the tip and root regions of the mating teeth such that the material removed compensates for the motion errors due to the change in stiffness. Assuming the tooth stiffness is linear with load, removing material linearly from each end of the tooth will achieve this cancellation (material removal is called tip relief or root relief, depending upon the region of the material removal). Figure 7 shows the tip relief starting at the highest point of single-tooth contact and progressing to the tip of the tooth. Root relief also varies linearly, and extends from the LPSTC to the SAP. The amplitude of the relief is equal to the single-tooth pair mesh deflection. The upper portion of Fig. 6 shows a straight-line profile chart for the perfect involute gear. The profile chart of Fig. 7 shows the linear shape of the profile modification along the tooth height. Figure 7 also shows that the transitions in tooth force are much more gradual, thus reducing the dynamic loads on the gear teeth. It should be noted that tip and root relief work well at minimizing the transmission error (TE) at the “design” load, but there will still be significant transmission error at other loads.

4.3 Effects of Load and Contact Ratio on Transmission Error

A popular approach to achieving gear designs that have lower transmission error is to increase the contact ratio of the gear pair, thus reducing the mesh stiffness

variation. This is done by either increasing the tooth height or by using helical gears. The total contact ratio of helical gearing is expressed as the sum of the profile contact ratio and the axial or face contact ratio:

$$m_t = m_p + m_f = Z/p_b + F/p_x$$

where Z and p_b were defined previously, F is the face width, and p_x is the axial pitch.¹³

A set of geometries (Table 1) used in an experimental noise study by Drago et al.¹⁴ will be used to show the effect of contact ratio on transmission error. Optimal profile and lead modifications have been applied to these gear pairs, and they have then been simulated^{15,16} to determine the effect of load on transmission error. The results for each case are shown in Fig. 8. Here, for the perfect involute spur gear pair, the transmission error increases linearly with load (the line is distorted due to the log scale on the y axis). The spur gear pair with profile modifications has increased TE at light loads and a minimum TE at the design load. If low transmission error is desired at no load, the gears must have a perfect involute over at least one base pitch of rotation. One means of achieving this is to use gears with a contact ratio greater than 2.0 and apply the relief at the highest and lowest points of double-tooth contact, respectively. A typical TE plot for a high profile contact ratio set is shown as case C in Fig. 8.

Figure 8 shows that the helical gears, which have circular profile and lead modifications, have lower transmission error than the spur gears, and, as helix angle and, hence, contact ratio is increased, the transmission error continues to be reduced. The following guidelines, based on increasing contact ratio, for reducing gear noise and vibration are:

- Increase tooth height (longer cutting tool, lower pressure angle) so that Z increases.

Figure 7 Transmission error and stiffness change for a modified spur gear pair.

Table 1 Design Data for the Gears Whose Data Is Plotted in Fig. 8

	Pinion	Gear	Pinion	Gear	Pinion	Gear	Pinion	Gear	Pinion	Gear
	<i>A, B</i>		<i>C</i>		<i>D</i>		<i>E</i>		<i>F</i>	
	Spur LCR		Spur HCR		Helical LCR		Helical MCR		Helical HCR	
Module (mm)	3.18		3.18		2.95		2.78		2.59	
Pressure angle (degrees)	25		20		23.5		22.2		16.5	
Helix angle (degrees)	0		0		21.5		28.9		35.3	
Profile contact ratio	1.43		2.10		1.37		1.37		2.12	
Axial (face) contact ratio	0.00		0.00		1.25		1.76		2.25	
Total contact ratio	1.43		2.10		2.63		3.13		4.37	
Tip modification (mm)	A:	B:	0.016		0.013		0.010		0.013	
	NoMod	0.019								
Total lead crown (mm)	—		—		0.005		0.010		0.008	

**Figure 8** Effect of contact ratio on the transmission error of different modified gear tooth pairs.

- Increase helix angle to decrease p_x .
- Increase face width (least practical in most cases).

However, the gear designer faces practical limits in each of these. For instance, tip thickness and root clearance constraints limit the tooth height, increased helix angle causes larger axial forces that cause bearing design difficulties (35° is a rough upper limit), and wide face widths result in larger deflections and load sharing difficulties. Another rule often quoted is that one should design to either an integer profile contact ratio or an integer face contact ratio, since either of these will provide reasonably constant mesh stiffness as the gears rotate. This concept works well when one is using perfect involutes, but if one is using tip

relief or lead crown on the teeth, it can be shown that the benefits of designing for integer contact ratios are reduced.

4.4 Other Gearing Types

The tooth profiles of most other gear types, such as spiral bevel, hypoid, and worm gears, are tied much more closely to their manufacturing process than are the profiles of involute spur and helical gears. Nonetheless, the excitations of these gears are similar to those of parallel axis gearing, with transmission error and mesh stiffness still being the major quantities to be concerned with.¹⁷ Again, tip relief and lead crown are used to compensate for stiffness variation, but now these terms are often described in terms of nonconjugate tooth curvature mismatch.

4.5 Other Excitations

As mentioned earlier, the time-varying forces due to friction and the change in location and direction of the net force on the gear may also provide a substantial force excitation, particularly when one has already minimized forces due to transmission error and mesh stiffness variation. These force variations are quite easily computed for parallel axis gearing and may also be evaluated for the other gear types. An example of a general force metric that includes each of these excitations is presented by Houser and Harianto.¹²

5 NOISE PATH ANALYSIS/DYNAMICS

The remainder of the solution of gear noise and vibration problems involves reducing the effects of the noise/vibration path to the receiver. Classical vibration modeling and modal analysis approaches that are discussed in other chapters of this handbook are often appropriate. However, one should be aware that the gear mesh frequency might be in the 2- to 10-kHz region where the modal densities of housing panels may be extremely high. In these cases, statistical energy analysis has been used for gear path analysis.¹⁸

5.1 Torsional/Lateral Dynamic Modeling

The first stage in the dynamic analysis of mating gears is to evaluate the torsional/lateral dynamics of the gear shaft system. The simplest acceptable model for evaluating gear dynamics is depicted in

Figure 9 Simple spring-mass model for gear dynamics prediction.

Fig. 9.¹⁹ Here, the gears are represented by both mass and rotary inertia, and the spring connecting the inertias at their respective base radii is called the gear mesh stiffness. This stiffness results from the sum of the tooth mesh deflections that result from Hertzian contact deflections, bending and shear deflections of the gear teeth, and the rotation and translation of the gear tooth base relative to the gear body. Each of these deflection components is of the same order of magnitude. A good estimate of the stiffness of a single tooth pair is 14×10^9 N/m per metre of face width. Since the stiffness of a rolling-element bearing is of the same order of magnitude as the mesh stiffness, one finds that there may be significant coupling between the gear translation and gear rotation. The two primary excitations of this model are time-varying mesh stiffness variation and the displacement input resulting from transmission error (depicted by a cam in the figure). More degrees of freedom must be added to the model if the forces due to friction (at a right angle to the line of action) or shuttling are to be included. When operating gears such that the mesh frequency resonance is excited, there is the likelihood of loss of tooth contact, and in these situations it is necessary to include a backlash nonlinearity in the model.²⁰

5.2 Housing Dynamics

After obtaining the forces at the bearings due to the gear excitations, the response of the housing to these forces is required. A simple asymptotic modeling procedure for performing such an analysis is shown in Fig. 10. Depending on the assumptions that are made, this model can range from being extremely simple to extremely complex.

An idler gearbox that has three gears and a total of six bearings has been used as an example for applying a simple version of this model.²¹ The average bearing force is used to excite a single panel of the housing, and the predicted mesh frequency noise level is shown in Fig. 11, as is the measured noise level. The asymptotic shapes of the measured and predicted responses are quite similar with the noise level of each plot having a low-frequency asymptote that increases with frequency at about 40 to 45 dB/decade. Data from other gearing applications have shown this slope to typically range from 30 dB per decade to 45 dB per decade.²² The noise level flattens or starts dropping above a frequency that normally corresponds to the major mesh torsional resonance.

If a speed sweep of the gearbox reveals gearbox resonances, then classical approaches must be used to identify the mode shapes of the subject resonances and then one must either attempt to shift the subject resonance out of the operating speed range or apply damping to reduce the resonant amplitude. The shaft bending and torsional resonances, which are often difficult to measure, will always be evident. For reference, the main torsional natural frequency of a steel gear pair is in the 2- to 8 -kHz frequency region, and shaft lateral vibration natural frequencies are typically lower than the main torsional natural frequency.

Figure 10 Noise prediction modeling procedure.

Figure 11 Mesh frequency order trace for an idler gear train.

6 GEAR RATTLE

Gear rattle is a lightly loaded phenomenon that is usually excited by time-varying torques in the drive system. Rattle is common in drive trains driven by an internal combustion engine where the prime excitation is at the engine firing frequency. Rattle results from the gear teeth losing contact so that they float in the backlash region and then come back into contact with repeated impacts. Although these repeated impacts have periodicity at the excitation frequency, one only hears the ringing impact response typical of the gears and their structural supports. The frequency spectrum of gear rattle usually shows an increase in broadband noise in the 1- to 5-kHz frequency region. The reduction of rattle may be achieved by minimizing backlash, but this is dangerous since manufacturing errors may result in tight mesh operation that could cause a significant increase in gear whine. Other approaches to minimizing rattle use system dynamics solutions such as providing a

backlash zone in the clutch or altering the system's mass-spring dynamics.²⁰

7 TROUBLESHOOTING

Most gear noise problems show up after a product is in production, and the gear noise solution becomes a troubleshooting issue. Listed below are some of the steps that should be taken to achieve a viable solution for such problems:

- Identify whether the noise is a whine problem, a rattle problem, or some other type of sound. This is normally done by simply listening to the gears but may require observation of the frequency spectrum of the noise. If a gear whine problem is identified, the next steps are recommended.
- Identify the fundamental frequencies of the whine noise from the noise frequency spectrum. If the noise is at mesh frequency or any of

its harmonics, proceed to the next steps. If the noise is at a ghost frequency, a noninteger multiple of mesh frequency that still increases with speed, one must look for slight undulations of the tooth surface that are the result of the manufacturing process.^{24,25} Solutions to ghost noise problems are usually achieved by altering some aspect of the gear machining process. Severe sidebanding is an indication of high torsional vibrations and/or a large eccentricity in one of the gears.

- Perform speed sweep measurements to determine if a resonance is causing the problem. Typically a waterfall plot or a color speed–frequency map is used for this purpose; however, this author finds that plotting the amplitude of individual harmonics of mesh frequency versus speed or frequency (called order plots) is particularly useful. Resonant problems have a wide range of solutions, but simply reducing the mesh excitation is an approach that should not be overlooked.

Table 2 Effects of Different Gear Design and Manufacturing Parameters on Gear Noise

	Direction to Reduce Noise	Noise Reduction (dB)	Comments
Number of teeth	Decrease	0–6	Lowers mesh frequency.
Contact ratio	Increase	0–20	Requires accurate lead and profile modifications.
Helix angle	Increase	0–20	Machining errors have less effect with helical gears. Little improvement above about 35°.
Surface finish	Reduce	0–7	Depends on initial finish — reduces friction excitation.
Profile modification		4–8	Good for all types of gears.
Lapping		0–10	Very effective for hypoid gears.
Pressure angle	Reduce	0–3	Reduces tooth stiffness, reduces eccentricity effect, and increases contact ratio.
Face width	Increase		Increases contact ratio for helical gears; reduces deflections.

Table 3 Effects of Other Factors on Gear Noise

Load	Noise typically increases with load.
Power	Noise typically goes up with power.
Speed	Noise increases at 30 to 45 dB/dec beneath torsional natural frequency. Resonances will affect response.
Module	Debatable, since decreasing causes increase in contact ratio, but increases the number of teeth.
Tooth height	Increases profile contact ratio, thus reduces noise but tip thickness provides a limit.
Contact line length	Was once felt to be important to keep constant but not that important for modified gears.
Recess action	Is favored due to lubrication considerations and the reduction in entering contact sliding.
Roll angle	Avoid contact at low roll angles, 8°–10° preferred.
Backlash	Little effect on gear whine, important for rattle.
Misalignment	If contact ratio reduces, noise increases. Use lead crown to minimize its effect.
Spacing errors	Little effect on mesh frequency noise, but for quiet gears, will affect the noise floor at all other frequencies.
Profile errors	S-shaped and concave shapes are bad.
Pressure angle error	Can considerably increase noise.
Lead crown	Compensates for misalignment; reduces noise of helical gears; can be effective with high contact ratio spur gears; should not be overdone.
Lubricant viscosity	Increasing tends to reduce friction and hence reduces noise.
Split path drives	Tend to be quieter, can phase gears; compactness tends to yield quieter drives.
Planetary gears	Special case of split path drive. Proper phasing is helpful, but shafts need concentricity and float.
Materials	Usually, gear load capacity determines material; effects are not as great as claimed.
Damping	Effective for reducing amplitudes at resonances; has been applied to reduce the effect of gear blank resonances; may improve rattle properties.
Bearing type	Plain bearings reduce noise relative to rolling-element bearings; preload can affect noise levels.
Housing mounts	Can reduce flanking noise path.
Tuned absorbers	Have been effective where resonances exist.

- If comparing results with predictions of excitations, it may be particularly useful to experimentally determine the effect of load on noise.
- At each torque, obtain the contact pattern using bluing or other type of dye that will wear off as the gears roll through mesh. If the pattern is near the edge of the teeth, this is an indication of severe shaft or gear tooth misalignment. Such misalignment reduces the effective contact ratio of the gear pair. The pattern that is observed always has an area that is greater than that of an individual tooth pair in mesh due to the thickness of the dye and the fact that the pattern is the sum of the patterns of all of the teeth that have meshed with the measured tooth.
- Obtain gear profile and lead measurements for use in ascertaining manufacturing difficulties.
- Using measured profiles and leads, perform simulations to predict TE and other excitations.
- Look into modifying the profile and lead modifications to minimize the noise, being sure to provide adequate lead crown to compensate for misalignment. However, one should be aware that manufacturing variations might provide a large amount of statistical variation in the noise levels, so robust designs that have a low sensitivity to manufacturing errors are desirable.²⁶
- When all else fails, the gears may need to be redesigned with higher contact ratios or the sound path from the gearbox to the listener must be altered. The latter approach would include adding isolators to the mounts of the gearbox or going to the extreme solution of adding a cover over the gearbox.

8 GEAR DESIGN SUMMARY FOR MINIMUM NOISE AND VIBRATION

Anytime general statements are made about how much a given design change will reduce noise, an appreciation for the noise level prior to making changes is required. It is easier to reduce the noise of a poorly designed and manufactured gear set than one in which noise was considered from the beginning. Nonetheless, Table 2 provides a summary of some observations that have been made by many investigators that indicates some of the gains that might be achieved by altering transmission designs.^{27,28} Beware!! The many reductions that are possible in the table are not additive in nature. Also, changing one design quantity inevitably changes other quantities, so it is difficult to determine the effects of individual changes. Table 3 briefly discusses the effects of other schemes that may be applied to reduce gear noise.

CHAPTER 70

TYPES OF BEARINGS AND MEANS OF NOISE AND VIBRATION PREDICTION AND CONTROL

George Zusman
IMI Sensors Division
PCB Piezotronics
Depew, New York

1 INTRODUCTION

Bearings are needed whenever one part of machine slides against another and can be classified as providing sliding or rolling contact. A sliding bearing typically uses a lubricant to reduce friction between sliding surfaces. A shaft and bushing bearing is known as a journal bearing. Bearings that provide sliding contact fall into three general classes: radial bearings that support shafts, thrust bearings that support axial loads on rotating shafts, and linear bearings that support parts in a straight line. Radial bearings are also called sleeve bearings. Rolling-contact bearings are often referred to as antifriction bearings.

Most vibration prediction and control techniques for bearings are based on signature and spectrum analysis. The root-mean-square (rms), shock pulse, kurtosis, high-frequency resonance technique, and eddy current direct displacement measurements are the main methods of bearing diagnostics.

1.1 Use of Rolling Bearings and Construction of Bearing Assemblies

Thrust bearings take radial (axial) forces acting on the rotor and fix its radial (axial) position with respect to the machine body. The bearing assembly usually consists of two bearings:

- Fixed and floating
- Two bearings fixed only in one axial direction (two-sided fixing)

Fixed Bearing The fixed bearing takes up the radial load and the axial load simultaneously in two directions. The cylindrical roller bearings with one flange-less ring may be used in a fixed support together with another (thrust) bearing that takes up the axial loads; in this case the thrust bearing is installed in the housing with a radial clearance.

Floating Bearing The floating bearing takes up only a radial load and makes it possible for the shaft and housing to make relative displacement with respect to each other. The axial displacement is performed either in the bearing proper (cylindrical roller bearings) or when the bearing ring is clearance fitted with the mating part.

Two-Sided Fixing For two-sided fixing, use is made of radial ball bearings and roller bearings that take up axial loads at least in one direction.

Internal Clearance in Bearings The clearance in a bearing is a value of displacement of one bearing ring with respect to the other in a radial direction (radial clearance) or axial direction (axial clearance).

The following types of clearances are distinguished in a rolling bearing:

- Prior to assembly—initial clearance
- After assembly
- Clearance in operation conditions—working clear

Lifetime of Rolling Bearings The life of a rolling bearing is understood as the number of revolutions (or hours of operation at constant rotational frequency) that the bearing may perform before fatigue failure indications appear on its parts.

In practice, the life span of the same type bearings exhibits wide variations even in the totally coinciding operating conditions. When selecting rolling bearings, two specific parameters are used in addition to other parameters: dynamic load capacity and rated life or basic dynamic load rating (L_{10}).

The service life of a bearing is understood as a time period within which the given bearing preserves serviceability under specified production conditions. The limit fatigue load (P_u) is understood as such a load on the bearing that in ideal operating conditions does not ever cause fatigue failure.

1.2 Causes of Bearing Failure

The first group of causes is incomplete scope of testing of restored bearings and rejected batches of *mala fide* manufacturers (manufacturing defects): The serious incoming inspection of bearings performed by a number of enterprises has shown that depending on the batch the bearings may contain up to 90% of defective pieces, though looking perfect at first glance.

The other group of reasons of bearing failure lies in defects of assembly and operation:

- Violation of lubrication conditions (quantity and quality), violation of maintenance conditions (40%)

- Wrong assembly, installation, and adjustment (30%)
- Wrong usage (off-design operating modes), high loads (pressure in radial and/or axial directions) and vibration (20%)
- Operation wear (abrasive or fatigue) and contamination (10%)

This distribution depends on the field of application of a rolling bearing. In transport vehicles the main reason of failure is fatigue. In the petrochemical industry the main cause is wrong assembly, installation, and lubrication. In the pulp and paper industry it is poor lubrication and contamination. The character of damage of rolling bearings depends on the cause of damage: By investigating a damaged bearing it is possible to determine the cause of defects and take measures to prevent systematic repetition of such defects in the future.

Fatigue The cause of fatigue lies in alternating transverse stresses developed in subsurface layers of raceways that cause cracks propagating toward the surface. When rolling over the cracks of rolling elements, spalling of material particles takes place. Spalling (rubbing) is developed under edge stresses and wear products brought together with lubricant.

The incubation period (until fatigue damage features appear) depends on the rotational frequency of the bearing, load, lubrication effectiveness, and cleanliness of the lubricant material. Fatigue spalling of rolling bearing elements (in normal operating conditions) develops rather slowly and is accompanied with the increase of noise and vibration of bearings, which permits detection of the damage and replacement of the bearing prior to its full destruction.

1.3 Inspection of Bearings

The purpose of bearing inspection is to detect the following (see Fig. 1):

- Disagreement of the temperature, oil level, and other parameters to be tested to the norms and standards
- Unusual noise, sounds, or vibration
- Spills or leaks of technical liquids (oils, lubricants) around the bearings
- Discontinuities or cracks of bearing body

Temperature Monitoring Increased (as compared with the normative value) temperature is evidence of abnormal operation of the bearing assembly and causes degradation of lubricant. It is necessary to register and analyze possible reasons. Prolonged operation at temperatures over 125°C causes essential reduction of the service life of a rolling bearing.

Noise Monitoring (Organoleptic) When in good condition, the bearing generates uniform, soft, humming (the so-called rustling) noise. Rattling, whistling, squeaking, or metallic (and other unusual sounds) noise is evidence of an abnormal state of the rolling bearing. The defects causing noise in bearings are irreversible and demand replacement of the bearing.

Visual Observation Seals protect the bearing assembly from dirt and keep lubricant inside the bearing assembly. Insufficient lubricant, change of color or darkening when contaminated, change of consistency, and the like are all factors that may cause fast deterioration of the bearing.

Visual Inspection of Bearings after Disassembly

For visual inspection a small mirror and a probe with a rounded end is used. The purpose of inspection is to detect local defects: burrs, dents, scratches, pits, cracks, mirror-polished spots, or change of metal colors (temper colors).

Vibration Monitoring Practically all defects emerging during manufacture, assembly, and operation of the rolling bearing (as a part of a machine) exert an influence on the vibration parameters. As defects are developing, macro and microgeometry of bearings

Figure 1 Parameters and defects found during inspection of bearings.

undergoes changes, friction force properties, and loading conditions change. Nonlinearity and anisotropy of the vibration signal appears; the ratio between the random component and the periodic component of the vibration signal changes; shock pulses emerge to excite a broadband vibration of the bearing assembly; a low-frequency vibration appears. Various strategies and approaches are used for monitoring the parameters of vibration of rolling bearings.

1.4 Main Methods of Diagnostics of Rolling Bearings

To ensure high reliability of diagnostics of the technical condition of bearings and to prevent their premature failure, it is necessary to perform complex research based on incoming inspection of the quality of bearings to be mounted, works on vibration adjustment, outgoing inspection (postrepair check) of the quality of restored machines, periodic monitoring of the temperature, vibration, and noise character, and visual observation of the state of the machine during operation. These measures make it possible to ensure a feedback that greatly enhances the nonfailure operating time and reliability of the machine.

The essential part of these works is vibration monitoring. Two groups of methods are widely adopted for the determination of the technical condition of rolling bearings and detection of defects.

The first group is based on separation and analysis of discrete components on certain frequencies of excited oscillations in the bearing. The diagnostic features are frequency components of the spectrum and characteristics of signal pulse shape associated with the characteristic frequencies of the bearings (see Tables 1 and 2): the pulse peak value (harmonic amplitude), the ratio of the pulse (harmonic) energy to the noise level, and the amplitudes of spectrum components at the pulse repetition frequency (harmonic). For analysis of these parameters use is made of vibration signal spectra in the range of 5 to $10f_i$, spectra of amplitude-modulated envelopes of narrow-band high-frequency components of the vibration signal in the range of 5 to 20 kHz, vibration forms.

The second group of methods is based on diagnostics of the technical condition of the bearing as a whole: In case of loss of serviceability it is necessary first of all to determine the necessity for the bearing replacement (i.e., to determine its technical state). The cause of failure may be determined later, if required, in the course of visual inspection of the bearing. The condition of the bearing is evaluated by the degree of development of degradation processes. The following may serve as diagnostic parameters: characteristics of amplitude distribution, moment characteristics (dispersion, excess), correlation and regression variances, amplitude discriminants, various parameters with the use of peak factor, and comparison of various vibration parameters in various frequency bands. During analysis of the latter, use is made of the rms values of vibration accelerations in the range of 15 to 40 kHz, the peak value and the rms values of vibration accelerations in the range of 1 to 10 kHz, and some others.

The best results are obtained in case of simultaneous use of all these methods. Several approaches (strategies) to the diagnostics of rolling bearings are used depending on the hours worked and design peculiarities of the machine.

1. Diagnostics in the process of operation of a rotor machine with coaxial shafts with initially installed defect-free bearings (practically all pumps, fans, etc.). It is possible to diagnose the condition of such machines with the use of minimum diagnostic methods: methods of the first and second groups are used, mainly frequency analysis of the vibration high-frequency envelope, parameters with the use of the peak factor, and comparison of various parameters of vibration in various frequency bands. In this case it is possible to perform the measurement "only one time."
2. Diagnostics in the process of operation of a rotor machine with mechanical transmission and initially installed defect-free bearings in the absence of defects during the machine assembly. Since the number of various contacting friction surfaces may be quite great (transmission elements, bearing elements) and the kinematics of transmission (bearing operating conditions) vary essentially as compared with the kinematics of a multishaft system with coaxial shafts, usually monitoring is used, or use of additional methods of analysis and parameters (e.g., cepstrum for transmission).
3. Diagnostics in the process of operation of a multishaft rotor machine with mechanical transmission for a wide range of defects with the possibility of obtaining a short-term prognosis of the technical condition of the machine. Presence of various contacting friction surfaces (bearing elements, transmission elements), integral kinematics of the multishaft rotor system with coaxial shafts and transmissions, influence of skew, violation of rigidity (deformations) and slackening, and shaft defects—all these require performance of a full-scale monitoring with the use of a detailed frequency analysis (spectra, spectrum envelopes, orbits, cepstrum, phase analysis, etc.).

When installing a new bearing, the probability of using a defective part should be minimized. It may be achieved by using items of known manufacturers and/or by incoming inspection of bearings. Compliance of levels of rms values of vibration velocity and vibration acceleration for definite frequency bands is checked during the incoming inspection at test benches to the requirements of specifications for rolling bearings with the aim to determine the class of the bearing as per the noise produced. Frequency analysis helps clarify the diagnosis.

To ensure long-term operation, outgoing inspection of machine assemblies containing rolling-element

bearings is performed after manufacture or repair. Tests (and primary running in of friction pairs in case of necessity) are performed on driven units with various values of rotational frequency and/or load. These procedures may be combined with operations on vibration adjustment: balancing in own bearings, adjustments, and the like. When performing the tests, the whole range of vibration analysis methods is used.

As the defect develops, passing various phases in the chain: cause—incipient defect—developed defect—developed defect with secondary damage features, the properties of the combination of forces that excite vibration undergo certain changes. To detect defects of assembly of bearings (in absence of outgoing inspection), a frequency analysis of high-frequency vibration is used. This high-frequency vibration appears as a result of modulation of friction forces. The contour characteristics are taken. Simultaneously, the difficulty of rotation of the shaft in the bearing is evaluated; the temperature of the bearing (support) is measured; the organoleptic analysis of the bearing acoustic noise is carried out.

For monitoring the defects of wear of the rolling and retainer surfaces in the course of development of the defect, a frequency analysis of high-frequency vibration of fixed elements and the bearing assembly housing is used. This vibration appears as a result of modulation of friction forces until the developed defect phase is reached. At the developed defect phase (particularly with secondary damage features), if a machine is going to be operated further, the main type of inspection becomes the vibration frequency analysis in the range with the upper boundary, 5 to $10f_i$ (or $50f_r$, or in the range of 10 to 2500 Hz) and simultaneous visual analysis of the signal shape.

1.5 Vibration Test Points

During machine vibration (condition) checking, the general rule to be followed is the following: Measurements should be performed on rigid elements of the structure in the point as close to the critical assembly as possible; the number of mating surfaces along the path of propagation of the signal should be minimal. By measuring the radial vibration, the sensor (if possible) should be located so that its measuring axis crosses the rotation axis in three main orthogonal directions with respect to the axis. It is necessary to take into account a number of peculiarities of the rolling bearings that can introduce essential corrections into the general approach. When testing the condition (vibration) of the rolling bearing proper, the optimum measuring point may be on the part that directly contacts the bearing (usually on the housing) in the area of the loaded zone of the bearing, from the side of rolling elements entry into the load zone; see Fig. 2.

The sensor fastening method should ensure obtaining the upper boundary of the frequency band when getting the spectrum and vibration shapes to 5 to $10f_i$ (usually up to 2500 Hz for the rotor rotational frequency of 50 Hz) while obtaining the spectrum envelope up to 25 kHz with the ultrasonic analysis up to 40 kHz.

Figure 2 Optimum point of measurement of high-frequency vibration (ultrasonic oscillations) during monitoring.

With the periodic monitoring, maximum use is made of the fastening methods with the use of magnets, probes, and special connections. More rarely used is fastening with the stud with the help of glue, mastic (wax), or adhesive plate. With continuous monitoring only threaded connections are used.

When performing measurements with the help of a magnet or probe, the surface in the measuring point zone is cleaned of old paint and dirt. The surface in the place of contact (for the magnet) should be smooth; the area should be not less than 0.5 cm^2 . To improve the acoustic contact and reduce the cavity-resonator quality, it is recommended to apply some plastic grease or low-viscosity oil on the surface to be measured.

When carrying out measurements with the help of a probe (indicator point), the latter should be reliably pressed to the surface to be measured; the measurement axis should be perpendicular to the surface of the machine; deviations for more than 10° are inadmissible. The recommended pressing force is 10 to 15 N .

For reliable use of the frequency analysis the following requirements should be met:

- The upper boundary of the vibration spectrum analysis frequency band should be selected not less than $50f_i$ or 5 to $10f_i$.
- Higher harmonics of the rotor rotation frequency should be absent in the filter pass band for separation of high-frequency vibration envelope (or other toothed harmonics); there should be no high resonator quality fields (coupled with the method of fastening or properties of the machine), and the mean vibration level in the band should be comparable with the level of noise in the low and medium frequencies and should exceed the level of intrinsic noise of the device by not less than 15 to 20 dB .

In the process of monitoring, it is very important to perform the series of measurements strictly in the same measuring point.

Taking into consideration the above-mentioned facts, two main approaches are used in selecting the place of measurement:

1. An approach oriented on identification of the technical condition of the rolling bearing proper and measurement (sometimes "one-time") of the parameters of the high-frequency vibration (frequency analysis of the envelope).
2. An approach oriented on identification of the technical condition of the rolling bearing proper and the machine as a whole and (periodic) measurement of the parameters of vibration in the whole frequency range (frequency analysis of vibration in the band up to 5 to 10 f_i and the high-frequency vibration envelope frequency analysis).

For each of the approaches there are own peculiarities (rules) for the selection of measuring points.

1. When the high-frequency vibroacoustic signal propagates in metal, it attenuates. Nevertheless, the attenuation is small over linear sections with the length of less than 0.4 m. Thus, with the overall size of the bearing housing less than 0.8 m, sufficient rigidity of the housing, bearing rotational frequency of less than 5 Hz, and quite sufficient spacing between the adjacent bearings, the measurements may be performed practically in any of the points.
2. With small size of gear case in which the bearings are located (e.g., most cradle-mounted pumps, small gear cases), the influence of

vibration of adjacent bearings in measuring points 7 and 8, and sometimes in the measuring points in the direction of bearing radius may be quite great, and it is not recommended to perform measurements in these points.

1.6 Types of Defects of Rolling Bearings and Their Generalized Diagnostic Features

Emergence of defects in rolling bearings causes the appearance of frequency components in the vibroacoustic signal, as presented in Table 1.

The expressions presented in Table 1 determine only the frequencies of the main harmonics (pulses) emerging in the vibroacoustic signal with various defects in the rolling-element bearings. Additionally, vibration on higher harmonics of these frequencies emerges, as well as vibration on a great number of combinational frequencies components (cumulative, differential) of the main frequency components. The levels of vibration of frequency components are determined by the type and degree of maturity of the defect, the properties of the loads, the condition of lubrication, the transmission characteristics of the bearing assemblies, and other reasons. The number of combinations of combinational frequencies may be so great that manual analysis becomes next to impossible to perform.

If the inner ring of the rolling bearing is fixed and the outer ring is rotational (e.g., wheel pairs), then the cage rotational frequency (f_{cg}) in the formulas of Table 1 should be changed by the frequency ($f_r - f_{cg}$). If the inner ring of the rolling bearing rotates and the outer ring is fixed (e.g., midshaft bearing in aviation engines), then the rotor rotational frequency (f_r) in the formulas of Table 1 should be changed by

Table 1 Formula for Calculation of Frequencies of Main Operational Failures of Bearing Parts

No.	Designation	Formula	
		For Fine Calculation	For Approximate Calculation (95%) with $\alpha = 0^\circ$
1.	f_{cg} Cage rotational frequency	$f_{cg} = \frac{1}{2} f_r \left(1 - \frac{d_{rol}}{d_{cg}} \cos \alpha \right)$	$f_{cg} \gg 0.4 f_r$
2.	f_o Frequency of tumbling of rolling elements over the outer race	$f_o = \frac{1}{2} f_r Z_{rol} \left(1 - \frac{d_{rol}}{d_{cg}} \cos \alpha \right)$	$f_o \gg 0.4 Z_{rol} f_r$
3.	f_i Frequency of tumbling of rolling elements over the inner race	$f_i = \frac{1}{2} f_r Z_{rol} \left(1 + \frac{d_{rol}}{d_{cg}} \cos \alpha \right)$	$f_i \gg 0.6 Z_{rol} f_r$
4.	f_{rol} Rotational frequency of rolling elements	$f_{rol} = \frac{d_{cg}}{2d_{rol}} f_r \left[1 - \left(\frac{d_{rol}}{d_{cg}} \right)^2 (\cos \alpha)^2 \right]$	
5.	f_r Rotor rotational frequency (inner ring)		
	α Angle of contact between rolling elements and raceways		
	Z_{rol} Number of rolling elements in the bearing		
	d_{cg} Diameter of rolling bearing cage (pitch circle, circumference passing through the centers of rolling elements)		
	d_{rol} Diameter of rolling elements in the bearing		

the differential frequency ($f_{r1} - f_{r2}$) (frequencies of rotation of rotors f_{r1} and f_{r2}), while the cage rotational frequency should be changed by the sum frequency ($f_{r2} + f_{cg}$). It should be added that the analysis of integral or peak levels of vibration is mainly used for such machines in specially selected frequency bands.

1.7 Peculiarities of Diagnostics of Rolling Bearings by the Shape of Vibration Signal: Recommendations on Clarification of the Results of Diagnostics

The shape of the signal changes drastically as the defects of the rolling bearing develop: The ratio between the periodic harmonic and random components of the vibration signal changes, shock pulses appear (in a number of cases they appear periodically), the signal may become asymmetric, and vividly pronounced modulation appears. The visual analysis of the shape of the signal may be an essential complement to the results of the frequency analysis. The diagnostic features may be difficult for formalization, but the reproducibility is quite high. The shape of the signal usually becomes asymmetric in case of emergence of cracks or damage of bearing elements. When a vividly expressed local defect appears on one of the rings, shock pulses may appear in the shape of the signal with the periodicity of the rolling elements tumbling over the local defect. In case of severe wear of the bearing, the vibration signal modulation is vividly observed.

One of the most important peculiarities that help diagnose rolling bearings is emergence of vibrations on frequencies not multiple to the rotor rotational frequency. Nevertheless, in case of the appearance of a number of defects associated with the wear of the inner ring, nonhomogeneous radial fit, slippage, violations of rigidity, deformations of the support system, skewing, backlash, coupling defects, and vibrations appear on the rotor rotational frequency and its harmonics.

For localization and identification of these defects it is necessary to have comprehensive information on the condition of all assemblies of the machine. It is necessary to perform a joint analysis of the results of monitoring in all measuring points with due account of the machine operating modes, to study spatial distribution of vibration, to carry out the phase analysis, and the like.

If changes of the vibration state of several bearing assemblies arranged on one shaft axis are detected, very often these are not defects of several bearings, but severe defects of only one bearing. Such defects may appear as a result of the emergence of additional dynamic loads on the bearings adjacent to connection couplings, for instance, in case of skewing and problems with the coupling.

Very often vibration measurements testify of a change in the technical condition of the assembly, but the results of inspection do not allow reliable identification of the defect. The reason for the change of vibration may be the change in the operating mode of the machine, the change in the operating conditions, and influence of adjacent machines installed in the same premise with the machine undergoing diagnosis.

During analysis of machine vibration, it is required to observe several parameters simultaneously. For instance, the changes may take place only in the signal spectrum or in the envelope spectrum, or the pulses may be observed only on time realizations with the duration of 4 to 8 s, and so forth. This indicates the starting stage in the development of the bearing defect, lubrication defects, or appearance of hydraulic shocks. It is necessary to perform repeated measurements; if the results of measurements coincide, it is required to monitor the development of the defect within several days until the monitoring data (change of the machine vibration state) allows one to identify the defect.

In addition to the recommendations given in this chapter, the user may take into account the general recommendations presented in other chapters.

2 DIAGNOSTICS OF ASSEMBLIES WITH SLIDING BEARINGS AND SEALS

A sliding bearing could be represented as a part of the shaft called the journal, center shaft, and the like, which rotates inside a space limited by the bearing shell. The liquid lubricant (sometimes gas, magnetic field) prevents boundary friction of metal surfaces of bearing parts during its normal operation. The same lubricant, by interacting with the rotating shaft due to friction forces, forms the so-called oil wedge that forces it to float along the dynamic balance curve—the higher the curve, the greater is its rotational frequency.

Some works (see, e.g., Refs. 1 to 14) are dedicated to the methods of vibroacoustic diagnostics of sliding bearings as compared with rolling-element bearings, though they are also weak points in many machines and mechanisms, for instance, in ship diesel engines, in turbo generators, in various types of pumps, compressors, turbines, and the like. This may be explained by a number of reasons. One of them, evidently, is that the sliding bearing possesses weaker vibration activity as compared with other assemblies of the machine; therefore, one has to deal with minute vibroacoustic signals of the bearing proper, which are lost against the background of “noise”—signals produced by other elements of the machine when the measurements are performed by built-in sensors. Another reason is the difficulty of diagnosing the avalanche-like process of degradation of easily melted coatings of sliding bearing shells.

Certainly, not every defect of the sliding bearing is shown in the vibroacoustic signal that accompanies the work of the bearing. Nevertheless, such important defects from the point of view of reliability and safety of operation of machines equipped with sliding bearings as nonuniformity of clearances, play, rubbing-in/jamming, chipping, or melting of shells are well pronounced and vividly seen in the vibration signal; these can be used as diagnostic features. Consider the main defects and their possible features.

2.1 Irregularities of Clearances in Sliding Bearing (Seal)

In ideally designed and manufactured machines of the rotor type, the same distribution of clearances in each

bearing along the shaft axis is realized during operation in the nominal mode. Practically, the difference of clearances is checked with the removed upper cap of the bearing by direct measurements of side clearances between the shaft and the lower half of the bearing shell along its length, then the vertical clearances between the shaft and the upper half of the bearing shell are checked for equal values; also the vertical clearance change is evaluated during floating of the shaft journal in the working mode. Naturally, during assembly the out-of-roundness of the shaft journal is checked, as well as the condition of its working surface.

What are the reasons of appearance of such a defect? The main reason of appearance of irregular clearances is nondesign transverse load on the shaft, most probably coupled with the skew of the bearing axis relative to the shaft axis or misalignment of the axes of the shafts.

What is the influence of this additional cross load on the vibration signal? One of the characteristic diagnostic features is the deviation of the shaft center from the designed position on the dynamic balance curve in the given rotation-load mode.

In the frequency range it means enrichment of the spectral representation with reverse frequency harmonics. It should be noted that if this spectrum were obtained for the electric machine, then the increased level of the second harmonic of the reverse frequency with respect to the first harmonic would testify of a possible defect of the electromagnetic system (see Chapter 78).

Usually it is considered⁴ that in the presence of a pure disbalance, that is, in the absence of other defects, including axis misalignments of various types, the shaft rotational frequency component predominates in the vibration spectrum. The experience shows that even when the rotational frequency harmonics have great amplitudes in the rotor machine vibration spectrum, it may happen that they are initiated exactly by the great disbalance and not by other reasons associated with the condition of the bearings or shafts. Therefore, as usual, it is helpful to attract additional information for clarification of the diagnosis.

When facing a situation like the above during vibration analysis, it would be good to study other possible causes of the emergence of components multiple to the rotational frequency. Thus, for instance, it may be out-of-roundness of the shaft journal (faced-like journal) that may generate the second, third, or even higher harmonic of the rotational frequency depending on the number of these "faces," as well as play of the shaft journal.

If the first defect is, more likely than not, intrinsic (apparently, only in exceptional cases it may be expected to appear and develop in the process of operation of the machine) and should be excluded with correct assembly of the equipment, the second defect may be a consequence of the development of the shaft crack (such cracks often appear near the thrust surfaces in places of concentration of loads). The vibration spectrum in this case shows an essential level of the

second harmonic of the rotational frequency. This is one of the indicative features. Much more informative is the feature obtained with slow rotation of the shaft, called "slow roll data." The high level of the second harmonic in this case is determined only by the play of the journal (naturally with the absence of ovality in it), since the response to the dynamic action is negligible due to the very low magnitude of this action at such low shaft speeds.

2.2 Abnormal Clearance Values (Looseness and Gripping): Brushing

Increased or reduced clearances in the bearings and seals emerging as a result of poor assembly or degradation of the technical condition of the machine during operation are not so bad by themselves as by the consequences of their impact on the machine behavior. The most important of such secondary defects in terms of service life and reliability of machine operation is brushing of rotating parts against fixed parts. Brushing of the journal against the sliding bearing shell, brushing of the shaft against the elements of labyrinth packing of the lubrication system, brushing of the impeller against the elements of the stator, and the like manifest themselves by appearance of shock pulses both in the radial and in the tangential directions (friction pulses), as well as by temporary change of rigidity, which is reflected quite naturally in the characteristics of the vibration process. The development of degradation phenomena causes local heating, disruption of continuity of oil (gas) film and boundary friction, rubbing, burrs and deformation of contacting surface, and the like.

The main types of movement of the shaft journal in the presence of *increased clearance* in the bearing, as considered in detail experimentally and theoretically in Ref. 2, may be normal when the balanced shaft rotates inside the bearing without boundary contact and defective, as listed below:

1. Constant contact of the shaft with the bearing (with insufficient lubrication—retrograde precession with continuous slippage in the direction of rotation, i.e., "breaking-in"; with flooded lubrication—direct precession with the rotational velocity, i.e., "slipping").
2. Periodic striking of the shaft against the shell (in this case precession may be direct or retrograde).
3. In case of horizontal position of a heavy shaft pressed by gravity to the lower part of the bearing, swinging of the shaft end appears as in a pendulum with the length equal to the value of the clearance measured along the lower arc of the bearing clearance.

Since the task of this publication does not include detailed description of all possible dynamic phenomena characteristic to such a state of the machine, we shall consider here only the events of shaft rotation

causing brushing, while some other defective states will be discussed in the following section.

The presence of play (clearance fit) of the bearing shell with quite considerable influence from the side of the shaft (e.g., due to its imbalance) may also cause strikes and hence brushing. The presence of tight fit (tight clearance) all over the circumference of the shell or seal may be easily determined during assembly either by hard turning of the shaft or by fast overheating of the bearing after the start. Therefore, we shall not discuss here the vibrodiagnostic features of this defect (more so, this defect is not likely to develop in the process of operation). What concerns partially tight clearance, its manifestations are similar to what has been described above, though there are some specific differences.

The most important feature of manifestation of these two bearing parameter deviations is brushing, as mentioned above. A transparent model of influence of this defect on the dynamics of the shaft is described in Ref. 5.

Thus, if part of the shaft rotation period is characterized by contact (or weakening of interaction) between the rotating and fixed parts of the machine, then the effective rigidity of the assembly changes for this time period. In the first case the "norm—touching" increases for some time, in the second case the "norm—play" decreases for some time. Correspondingly, the mean rigidity value for this period slightly changes, which causes change of the own frequency of the assembly, as is known, proportionally to the square root of the rigidity value.

Such change of system parameters within the course of one cycle (or sometimes over a longer period) associated with greater (in amplitude) radial and tangential pulses brings about the appearance of nonlinear oscillations causing the following. In addition to the proper frequency of the assembly, if the rotational frequency exceeds 2, 3, or 4 times the modified proper frequency, then self-excited oscillations appear on the corresponding subharmonic. In this case, apparently, self-adjustment of rigidity and damping parameters of the assembly is performed within a certain range and, correspondingly, adjustment of the proper frequency so that the range of "harmful" rotation speeds exciting strong subharmonic oscillations becomes wider than the band of the resonance curve unmodified by the defect. If the shaft rotation speed is increased, then the value of the self-excitation frequency at a certain moment jumps over to the next least ratio ($\frac{1}{3}$, e.g., after $\frac{1}{2}$), and so on.

What concerns oscillations on the rotational frequency, due to nonlinear conversion of the torsional oscillations into radial, the amplitude of the first harmonic (1X) may grow with not so intensive brushing; but due to considerable damping with a severe defect, it falls down (though in this case the vibration of the housing may grow considerably). The maximum rise on the Bode diagram will be higher (in revolutions) for the tight clearance (i.e., for the norm—touching version) and lower for the looseness case (i.e., for the norm—play version) due to modification of the proper

frequency value. As always, for nonlinear oscillations the Bode diagrams differ greatly for rising and for lowering down of the revolutions.

The vibration spectrum may contain not only the rotational frequency and its subharmonic, but also their multiples; this is explained by the pulse influence of the defect.

When measuring relative vibrodisplacements of assemblies with such defects, it is useful to evaluate the position of the shaft center in the clearance (since its anomalous displacement is one of the main reasons of brushing) and the shape and swing of the orbit,⁵ unambiguously shows the moments when the clearance between the shaft and the shell is taken up in the different modes.

With this defect, the position of the shaft center may sharply change both in the stationary modes and in the speeding-up and running-down modes. The spectral composition, orbit shape, and direction of precession of each frequency component may be evaluated by full vibration spectra.

In Refs. 8 and 13 it is shown that if rub occupies the whole perimeter of the shell or seal the orbit is a circumference, and the precession is retrograde, on the modified proper frequency. Thus, in the presence of brushing some of the following features may be manifest in relative vibration^{5,13}:

- Change of vibration on the rotational frequency 1X
- Abnormal shape of the orbit
- Subharmonic vibration
- Components with retrograde precession
- Harmonics in the spectrum
- Changes in the mean position of the shaft, and some others

Since the phenomena taking place in the presence of such defects in the machine are essentially nonlinear, then the minutest changes in the assembly operating conditions cause considerable changes of oscillation characteristics. Therefore, when making a decision it is recommended to consider all the above-mentioned characteristics together, as a set.

When measuring vibration on the housing with the help of accelerometers, the above-mentioned characteristic features are not obtainable, but other features are manifested. Amplitude spikes corresponding to the moment of defect flicker in the contact zone appear in the region of one of the proper frequencies of the machine and the resonance frequency of the sensor. Since they create the modulation of these frequency components of great depth, the spectral characteristics of the amplitude envelope are a sensitive feature of the defect. An additional characteristic feature in this case is the appearance of frequency modulation of excitation frequencies (but not resonance frequencies!), since the pulse tangential forces emerging during boundary friction create a modulation of the torque that disrupts smooth rotation of the shaft. The spectral components

of the amplitude and frequency modulation are used as diagnostic features of brushing and burring.

The amplitude modulation manifests itself in a wide range of frequencies; its depth is the greatest in the vicinity of the resonance frequencies of the assembly or the measuring device. As a rule, the frequency modulation, by the rotational frequency and its harmonics, also manifests itself in the vicinity of the main excitation frequencies (blade, impeller, toothed, etc.). (It should be noted that this parameter is most sensitive in the case when the torsional oscillations of the shaft are measured directly.)

There is one more informative parameter of the vibration process that is sensitive to the process of touching and burring at the initial stage. It is kurtosis of the frequency curve of instantaneous vibration values in a wide or narrow informative frequency band. As a typical example it is possible to state experimental data⁸ obtained during diagnostic testing of a water centrifugal turbopump. Burring of sliding bearing shell (using water lubrication) was simulated in the process of testing. Shaft touching the bearing shell, which caused burring of shaft surfaces, was stimulated by interrupting the supply of lubricant. Starting from this moment the process was developing increasingly. The swing of kurtosis change Δu of the vibroacoustic signal was particularly great in the vicinity of proper frequency of the assembly at the initial moment of defect development. Its mean value also grows fast at the early stage of assembly degradation. Then upon reaching the maximum value, it even starts decreasing. Such behavior of the given features is generally characteristic of the defects whose development is associated with appearance and increase of the number of pulses in the vibration signal. They are very effective for early diagnostics.

Since the development of this defect is difficult to predict, the features may vary widely in the process of operation of the machine; this makes it necessary to compare large quantities of information in order to obtain a reliable and thorough diagnosis.

2.3 Defects of Shell Surfaces

In practice, it sometimes becomes necessary to deal with shell surface defects appearing as a result of errors during assembly or wrong operation (chipping, melting out of babbit, etc.). The features of this defect are similar to the features of irregularities of clearances in the bearing. Some difference is due to a greater number of harmonics of the rotor rotational frequency as a result of considerable change of the signal shape. There is a characteristic feature stable to the mode change. It is based on a greater diagnostic value that the information on the phase relationships between the rotational frequency harmonic characteristics for this defect acquires, particularly the information on different vibration signals. For example, when conducting research of the features of bearing shell chipping, the Lissajous figures (very sensitive exactly to phase information) for the signals of relative vibration built up for the first harmonic of vertical vibration and third harmonic of horizontal vibration have changed shape and

acquired a characteristic form only in the presence of a defect independent of the load, rotational mode, and construction characteristics of the bearing.

2.4 Self-Exciting Oscillations on an Oil Wedge

Mechanism of Excitation of Oscillations In certain conditions very intensive low-frequency vibrations appear in the rotor-type aggregates, these vibrations being nonmultiple to the rotor rotational frequency. In most cases it is associated with the loss of dynamic stability of the rotor rotation emerging when the circulation forces of the oil film and/or aerodynamic circulation forces exceed the damping forces. This phenomenon is characteristic of the bearings having cylindrical or elliptical reboring of the shell and is frequent for high-speed aggregates with light rotors, aggregates with vertical rotor rotational axis, machines with low load on the bearings or with relatively long (with great contact area) thrust portion of the bearing. Loss of dynamic stability is induced by the reduction of load (i.e., unloading) of the bearing, increase of lubricant viscosity, problems with the bypass or overflow grooves, increase of clearances in the bearing, skewing of the shell axis with respect to the rotor (journal) axis, unbalanced relief steam force, and the like. It should be noted that though the discussion here is for the sliding bearings, these phenomena in principle are attributable to all assemblies consisting of two cylinders, one in the other, separated with lubricant and rotating relative to each other.

The main reason for the dynamic instability of rotors in sliding bearings is the behavior of the lubricant rotating in a narrow clearance between the shell and the rotor, an important characteristic of which is the relative mean rotational velocity. If the shaft is not sufficiently loaded for some reason, the shaft center is located near the bearing cross-sectional center. While picking up rotation speed and approaching the stability threshold, the shaft comes closer to the bearing walls as a result of orbit precessing (the dynamic eccentricity grows, while the static one remains close to zero). It means that the rigidity of the bearing changes, hence the stability threshold also changes. When the latter becomes equal to the rotation speed, oscillations of the limit cycle on this new proper frequency appear; they correspond to the given rigidity. In Ref. 9 it is shown that a feedback appears between the rotor oscillations, its revolutions, and threshold. Thus, at any constant speed above the threshold, the increase of the orbit swing increases the rigidity and displaces the threshold up, this causing the decrease of oscillations that, in their turn, immediately influence the rigidity. The threshold is reduced, the oscillations start rising again, and the whole process is repeated, maintaining a definite oscillation swing. With the rotation speed increase, the proper frequency and the threshold grow, gradually remaining subsynchronous, and the oscillations being governed by the same mechanism are gradually increasing in amplitude, while their frequency (changing proper frequency) follows the

changes of the rotor rotational frequency also in a subsynchronous manner.

Though the oscillations in the bearing may not exceed the clearance value, the shaft experiences considerable flexing impact, and this causes secondary defects of the type of rotor touching stator; this makes the modes of self-excited oscillations on the oil wedge very destructive and dangerous.

Oil Whirl and Oil Whip The experience of operating aggregates equipped with flexible rotors shows that reduction of stability and appearance of highly intensive resonance oscillations on the oil film are more characteristic of rotors with the working rotational frequency exceeding the first critical rotational frequency of the rotor, but less than the double first critical rotational frequency. In most cases the oil whirl is associated with an essential unloading of the bearing.

The oil whirl causes intensive vibration at the frequency, 0.3 to $0.48 f_r$. This vibration is determined by the direct precession of the shaft in the bearing under the action of the lubricant, which can be determined both by the filtered orbits and by the full spectra.

The influence of the oil whirl on the shape of the trajectory of the shaft journal movement in the bearing is that, depending on the ratio between the synchronous component and the subsynchronous component, it is

close to circle, or it has also an inner loop rotating in opposition to the rotor rotation.

As distinct from the oil whirl, appearance of such self-excited oscillations as of the type of oil whip happens in rotors with working rotational frequencies two and more times exceeding their first critical frequency and requires the supply of external energy to feed the whirl. It is associated, for instance, with the influence of vibration or load. The oil whip also causes intensive vibration of the sliding bearing on the frequency close to the first critical frequency of rotation of the rotor, only as distinct from the first case it does not readjust itself following the changing rotational frequency, but remains practically independent of the revolutions.

Since considerable oscillation amplitudes with unstable shaft oscillations may cause touching, it is possible to avoid the manifestations of such destructive defects by using a number of constructive methods:

- With two longitudinal grooves
- With three longitudinal grooves
- With lemon-shaped boring
- Geometric center of pad
- With displaced shells
- With mobile shell pads
- With oil pockets

Table 2 Manifestation of Defects of Sliding Bearings in Full Spectra and Orbits

Type of Defect	Relative Frequency	Direction of precession		Notes
		Direct	Retrograde	
Partial rub	$1 \times$	+	+	Components $1 \times$ and $2 \times$ behave as in the case of unidirectional radial load: the amplitude of the reverse component grows, and that of the forward component goes down with the development of touching.
	$2 \times$	+	+	
	$\frac{1}{2} \times, \frac{1}{3} \times, \dots$	+	+	
Full annual rub by rotation angle	$1 \times$	+	—	Depending on dry friction between the rotor and the seal, its yield characteristic, attenuation, and imbalance values, the system may display either a forced response with predominance of the direct component $1X$ or a resonance response with predominance of the retrograde component.
	Proper frequency of pair: rotor seal	—	+	
Oil whirl	λX	+	—	Dominating direct orbit with the inner loop (combination of the whirl component and component $1X$). In the full spectrum it is revealed as subharmonic direct component.
	$\lambda = 0.3, \dots, 0.49$			
Oil whip	Fundamental rotor frequency	+	+	Dominating direct orbit with the inner loop (combination of the whip component and component $1X$). In the full spectrum it is revealed as subharmonic direct component. Usually small retrograde components of $1X$ and subharmonics are present due to anisotropy of support rigidity.
Whirl breakaway	λX	+	—	The whirl breakaway may be distinguished from self-excitation on the oil wedge by its disappearance while the flow through the compressor increases. The full spectrum resembles greatly the spectrum of the oil whirl.
	$\lambda = 0.1, \dots, 0.8$			

The most effective version is the version with hydrostatic bearings, since constant maintenance of high pressure of oil allows starting the machine without the usual shortcomings and does not require large clearances due to more stable position of the shaft in the machine clearances; besides, it helps prevent the possibility of self-excited oscillations.

In conclusion, let us present some of the described relationships and their manifestations in Table 2, which is adapted from Refs. 8 to 14.

CHAPTER 71

CENTRIFUGAL AND AXIAL FAN NOISE PREDICTION AND CONTROL

Gerald C. Lauchle

Graduate Program in Acoustics
Pennsylvania State University
University Park, Pennsylvania

1 INTRODUCTION

Axial-flow fans are air-moving devices that draw air into a rotating blade row—called a *rotor*—in a direction that is parallel to the axis of blade rotation. The expelled air is also directed axially, but there may be some rotational velocity components in the discharge. This is called *swirl*. *Centrifugal fans*, also called *centrifugal blowers*, draw air into the rotor, or *impeller*, axially, and then by design, turn the flow 90° and expel it radially.

Fan noise control does not usually involve modifying the fan itself because such noise control modifications almost always result in a degradation of the aerodynamic performance of the fan. Engineers are foremost concerned with the volumetric flow rate and pressure rise required for an application. Noise is a secondary factor, the control of which is usually performed on the propagation path and surrounding structures.

2 AIR-MOVING DEVICES

This chapter is concerned with the predicting and controlling of sound radiation from axial-flow fans and centrifugal blowers that operate at subsonic Mach numbers, based on the rotor tip speed. This sound radiation is considered as noise, noise that is due predominantly to aerodynamic sources. Fan and blower noise is a class of flow-induced noise. Detailed descriptions of the fundamentals of flow-induced noise are given in Chapter 9. Attenuation of fan noise in ducting systems is covered in Chapter 111, while Chapters 89, 90, and 91 deal with the aeroacoustics of high-speed jet and rotor noise.

Here we introduce various methods that may be used to estimate fan and blower noise emissions. For completeness, we will define relevant fluid flow concepts as required for the sound generation processes. From the outset it must be made clear that flow-induced noise generation for even the simplest of flows is a very complicated process that involves unsteady flow, stochastic turbulent flow, fluid–structure interactions, and acoustic wave propagation. Exact formulations are not generally possible, so we rely upon empirical models and simplified theory to describe the radiated sound pressure or sound power from fans and blowers of various complexities.

The most common types of small, subsonic air-moving devices are *centrifugal blowers*, *axial-flow*

fans, *plenum fans*, *cross-flow fans*, and *laminar-flow fans*. The laminar-flow fan moves air by the action of viscous drag on rotating disks rather than by lift created on rotating blade rows. The noise is obviously very low from these devices because there is no unsteady flow or turbulence, but their efficiency is not particularly high either. The reader is referred to Schlutt and Dowling¹ for a description and aerodynamic performance of such devices.

On a similar note, the acoustics of cross-flow fans—or *tangential fans*—is not very well documented. Cross-flow fans are widely used for air conditioners, air curtains, car ventilators, and household heaters. They have a drumlike impeller that is usually very long in comparison to the diameter. Figure 1 shows a schematic² of the flow field in such devices. The field is characterized by the double passage of air through the impeller blades and by the formation of a vortex within the impeller. Design goals for the cross-flow fan are centered about the position and strength of this vortex, which greatly affects performance and efficiency. Because the impeller length can be varied almost at will to produce the desired volume flow rate, the impeller speed is kept low. This low speed makes cross flow-fans inherently quiet. This type of air-moving device has thus not received much attention from the noise control engineering community, although Koo³ describes an experimental study of the effect of casing design on noise. We will not consider further the cross-flow fan in this chapter.

Typical axial-flow fans used for ventilating and cooling purposes are shown in Fig. 2. Axial-flow fans can be configured with or without guide vanes, and they can be operated either in or out of ducts. The fans of Fig. 2 are seen to be encased in short cylindrical ducts. Regardless of the duct length, this feature identifies such a fan as a *tubeaxial* fan.

A *vaneaxial* fan is similar to the tubeaxial except that the duct is long enough to support inlet and/or outlet guide vanes, as illustrated in Fig. 3. The guide vanes are aerodynamically designed to improve the flow in the vicinity of the rotating blades, to take the swirl out of the downstream flow, and to generally improve the performance and efficiency of the fan. The energy that would be in the swirl is effectively converted to static pressure rise by downstream guide vanes. When no aerodynamically shaped guide vanes

Figure 1 Schematic of the flow field in a cross-flow fan.

Figure 2 (a) Schematic and (b, c) photographs of typical axial-flow fans.

Figure 3 Schematic of a vaneaxial fan.

are used and the fan is operated in the open air, it is called a *propeller* fan, as illustrated in Fig. 4.

Centrifugal fans are composed of an impeller that operates within a volute housing, or *scroll*. The impeller blades may be canted in the forward, backward, or radial directions. Figure 5 illustrates the forward-curved impeller configuration. Air enters the impeller axially where the lift created by the rotating blades turns the flow 90° , directing it along the walls of the volute and eventually discharging it through the exit duct. Forward-curved blades direct the air into the scroll with a velocity greater than the tip speed of the impeller. These types of fans operate at relatively low speeds for a given pressure rise and airflow requirement. The low speed does not

usually imply low noise, however, because the blades support highly separated flow that leads to broadband turbulence noise.

Backward-curved impeller blades discharge air that has a relative velocity less than the tip speed. For a given airflow and pressure rise requirement, this type of fan operates at a higher wheel speed than does the forward-curved device, but because the aerodynamics are better, it is usually a quieter blower.

Radial blowers are rarely used for ventilation or cooling. They are used to move dust and particles. The speed of the air leaving the radial blades is essentially equal to the tip speed of the impeller. The pressure rise remains quite constant over varying volumetric flow rates. Because of intense pressure pulses that are created as radial blades pass by the tongue of the discharge, such fans are prone to producing annoying tones.

Air may enter on one or both sides of the impeller of a centrifugal blower leading to the distinction of *single-inlet* or *double-inlet* configurations, respectively. The single-inlet blower has one impeller wheel, while the double inlet typically has two impellers tied to the shaft of a common motor located between them.

Mixed-flow blowers usually have radial discharge blades along with a set of inlet blades that are aerodynamically shaped to improve the turning of the flow from an axial direction to the circumferential direction.

Plenum fans are backward-curved impellers that are mounted in rectangular plenums. They are used in many air-moving applications including room circulation, duct flow, roof and wall exhaust, and cooling of electronic components in cabinets. Figure 6 shows a typical motorized plenum fan. An axisymmetric inlet guide ring helps direct the inlet air axially into the

Figure 6 Photograph and schematic of a typical backward-curved plenum fan.

core of the fan. The air is turned by the suction of the rotating blades and discharges tangentially in all directions; there is no scroll casing surrounding the rotor. In the absence of a scroll and cutoff, these fans produce little discrete-frequency noise. Acoustic emissions are broadband, apparently due to inlet turbulence, blade

passage turbulence, and trailing-edge noise-generating mechanisms.⁴

3 AIR-MOVING DEVICE PERFORMANCE

By way of nomenclature, the following definitions are used in this chapter:

B	number of rotor blades
N	rotor speed (rev/s, rps)
Ω	rotor speed (rad/s)
D ($2R$)	diameter of rotor (m)
D_h	hub diameter (m)
Q	volumetric flow rate (m^3/s)
ΔP	static pressure rise (Pa)
u_{tip}	tip speed of rotor (m/s)
ϕ	flow coefficient
Ψ	static pressure coefficient
BPF	blade pass frequency (Hz)
U_∞	flow velocity through fan (m/s)
ρ_0	air density (kg/m^3)
η_s	static efficiency
Π	input shaft power in kilowatts (kW)
SHP	input shaft power in horsepower

$$\Psi = \frac{\Delta P}{\frac{1}{2} \rho_0 u_{tip}^2} = \frac{2 \Delta P}{\rho_0 \pi^2 D^2 N^2} \quad (3)$$

$$\eta_s = \frac{Q \Delta P}{\Pi} \quad (4)$$

$$BPF = NB \quad (5)$$

Air-moving device performance can be determined using the Air Movement and Control Association (AMCA) Standard 210.⁵ Such performance is indicated by a *fan performance (head-flow) curve* as shown in Fig. 7. The performance curve depends on fan speed. The *system resistance curve* is based on the losses in the system where the fan is to do work. The energy equation is used to get this curve; that is why it is quadratic in Q . Where the two curves cross is called the *operating point*. It is noted that plots of pressure coefficient versus flow coefficient results in a single curve for the same fan operating over different conditions. The fan performance curve will change significantly when the device is operated at altitude (e.g., fans in aircraft). Figure 8 shows the effect.

4 GENERAL FEATURES OF NOISE RADIATION FROM AIR-MOVING DEVICES

Various mechanisms cause noise from fans as summarized in Fig. 9. One of the more important causes

Interrelationships include:

$$u_{tip} = \pi N D \quad (1)$$

$$\phi = \frac{U_\infty}{u_{tip}} \quad (2a)$$

$$\phi = \frac{(\pi D^2/4) U_\infty}{(\pi D^2/4) u_{tip}} = \frac{4Q}{\pi^2 D^3 N} \quad (2b)$$

Figure 7 Sketch of fan performance curves and a system resistance curve. The intersection of these curves defines the operating point.

Figure 8 Fan performance and system resistance curves change when the fan is operated at different altitudes.

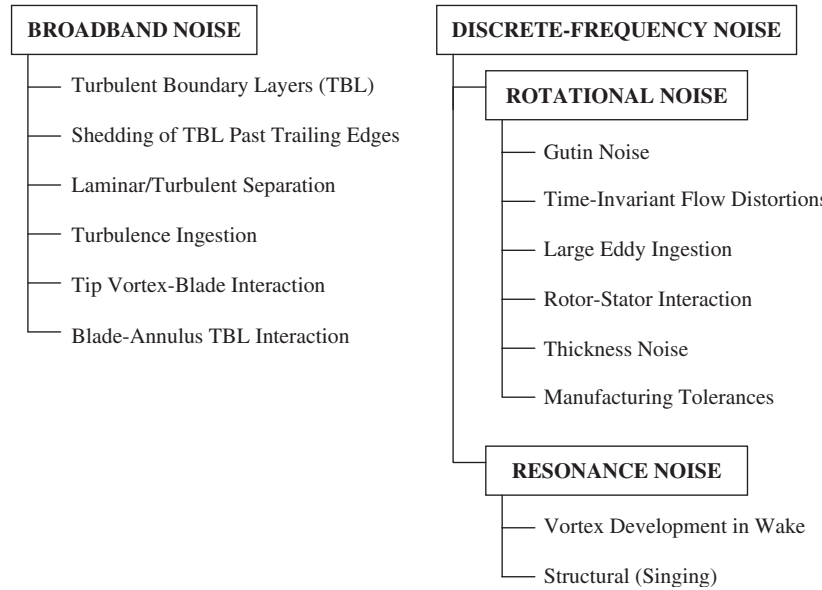

Figure 9 Mechanisms of fan noise generation.

of discrete-frequency noise is the passage of rotating blades past fixed obstructions. The obstructions cause time-invariant flow distortions that each blade responds to as it goes by it. The response is in the form of periodic changes in blade lift and drag due to local changes in blade relative velocity and angle of attack. For equally spaced blades the noise is radiated at harmonics of the blade pass frequency (BPF).

Basic flow noise theory shows that dynamically changing forces—blade lift and drag in this case—result in dipole sound radiation. Modeling of this type of noise is therefore confined to modeling the periodic force fluctuations. In the case of the acoustic wavelength being larger than say the fan diameter, the dipole radiation is *compact* and is easily computed from the force fluctuation, for example,

$$P(r, \omega) = \frac{i\omega \cos \beta}{4\pi r c_0} F(\omega) = \frac{ik_0 \cos \beta}{4\pi r} F(\omega) \quad (6)$$

where $P(r, \omega)$ is the Fourier transform of the radiated sound pressure at radian frequency ω due to force F , c_0 is sound speed, $k_0 = \omega/c_0$, and β is the angle measured from the direction of the force to the field point r . The *power spectrum* of the sound pressure is computed from Eq. (6) according to

$$\begin{aligned} \Phi_{\text{rad}}(\omega) &= \frac{\langle P^*(r, \omega') P(r, \omega) \rangle}{\delta(\omega - \omega')} \\ &= \frac{k_0^2 \cos^2 \beta}{16\pi^2 r^2} \Phi_f(\omega) \end{aligned} \quad (7)$$

where $\Phi_f(\omega)$ is the power spectrum of the force fluctuations. Chapter 42 provides details on spectrum analysis.

The delta function appearing in Eq. (7) is a reminder that individual frequency components of a power spectrum are statistically independent of each other. Note also that the delta function has units of ω^{-1} (s) and the units of $P(r, \omega)$ are $\mu\text{Pa s}$. The spectrum therefore has units of $\mu\text{Pa}^2 \text{ s}$ or $\mu\text{Pa}^2/\text{Hz}$ when cyclic frequency ($f = \omega/2\pi$) in hertz is used. It is not our intent to oversimplify this analysis! It can be simple as indicated, but at higher frequencies, where the wavelength of sound becomes smaller than the characteristic fan dimension, the radiation is much more complicated. This is the condition of *noncompact* radiation and must be treated as special cases for each given mechanisms.

The loading on a fan has a considerable influence on the radiated noise spectrum. Figure 10 shows a sequence of measured spectra on a small computer cooling fan, each for a different operating condition. Spectrum (a) is for the free delivery condition, and the spectrum is rich in harmonic tones with a fundamental at the blade pass frequency. Overtones are labeled 1, 2, ... As the loading on the fan is increased (indicated by lower flow rates), the rotor blades begin to stall and a great deal of turbulence and vorticity is created. These are broadband noise mechanisms and the broadband noise masks the discrete-frequency radiation.

Interaction tones occur when fixed obstructions are placed in the fan inlet or outlet. Figure 11 illustrates this situation. The wake from the obstruction contains a velocity defect. As each blade in the rotor passes through this wake velocity defect, a dynamic change

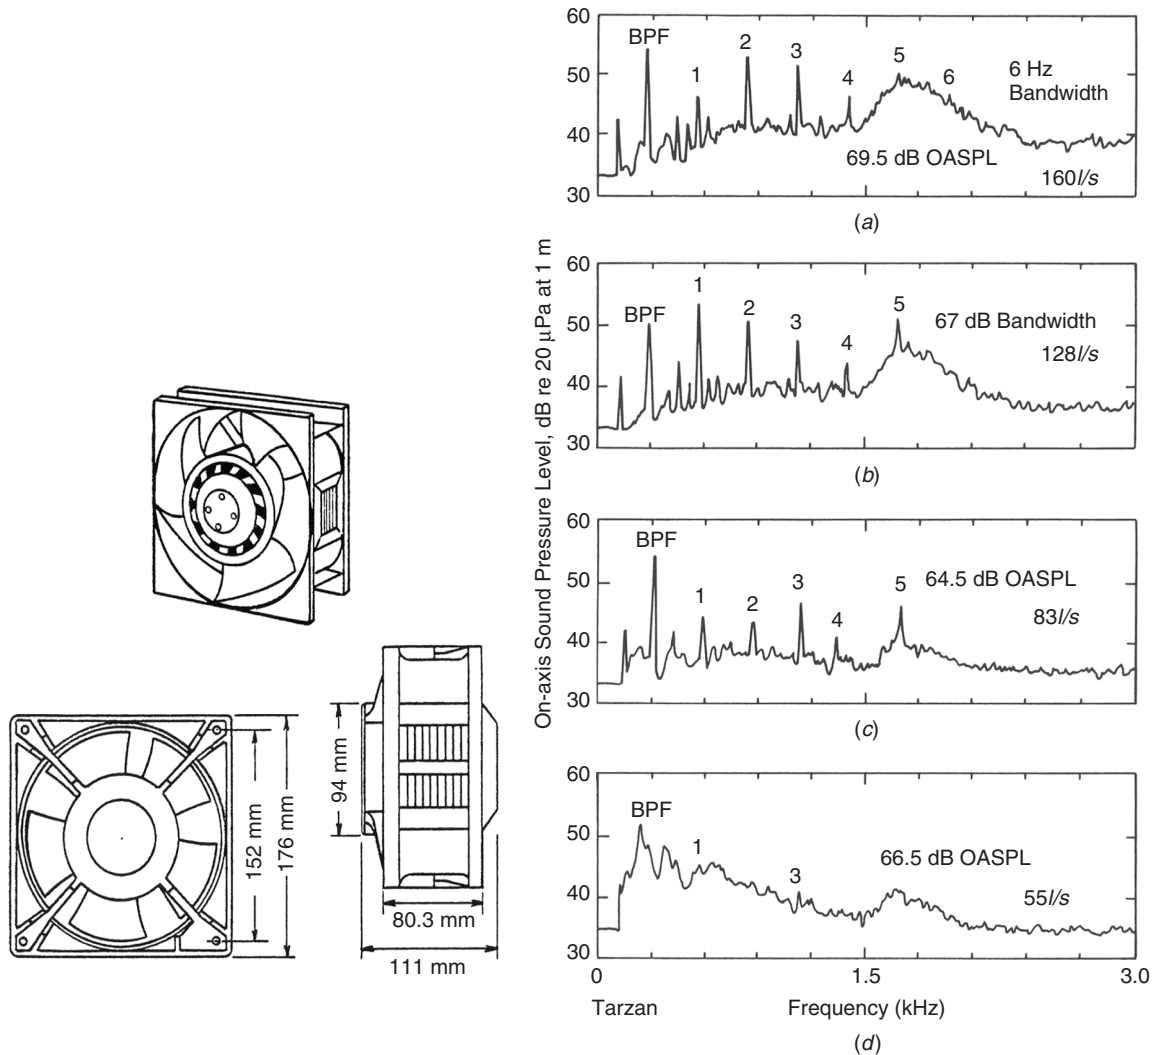

Figure 10 Sound pressure spectra measured by Fitzgerald and Lauchle⁶ on a Rotron Tarzan fan. The volumetric flow rate through the fan is decreasing from (a) through (d).

in the blade force occurs, and dipole radiation is set up at the frequency of the blade pass. In the example shown, a cylinder spans the fan inlet; thus, each blade passes through the cylinder wake twice per revolution. A strong second harmonic of the BPF is thus created. As seen on the graph, the level of the second harmonic (first overtone) is larger than the fundamental. These levels diminish rapidly as the obstruction is moved away from the fan. The results indicate that fan installation must be carefully performed to avoid obstructions that lead to time-invariant flow distortions that then lead to tonal noise production.

Figure 12 shows the variation of spectral character of the radiated sound power from a forward-curved centrifugal blower operating at constant speed but

under different static pressure conditions. For this blower, the best static efficiency point is at 1.22 in. of H_2O (304 Pa). It is interesting to note that the noise is predominantly broadband for this condition, low in level, and free of blade pass frequency tones. Blade pass frequency tones appear for off-design operating conditions, which is typical of forward-curved centrifugal blowers.

5 EMPIRICAL NOISE PREDICTION FOR AXIAL AND CENTRIFUGAL FANS

Fan noise prediction can be performed using simple empirical formulations, or if time, expertise, and resources exist, from detailed analysis, computational fluid mechanics, and computational aeroacoustic

Figure 11 Experiments by Washburn and Lauchle⁷ show that the sound radiation at the harmonics of the BPF are strongly affected by the location of a fixed obstruction placed in the fan inlet.

codes. In this chapter, we provide relatively simple methods of predicting the tonal and broadband noise components of axial and centrifugal fans. The empirical approach is basically adopted, although for some of the fan noise mechanisms, supplemental analytical formulations are included. In most empirical methods the overall noise level is estimated, while in others the spectrum can be determined. In regard to the former, an acoustic quantity called the *specific sound power level* was defined by Madison⁸ to be

$$H(\phi) = \frac{W}{\Delta P^2 Q} \quad (8)$$

where W is the overall *sound power* in watts. Consider the variation of W with physical parameters under the

condition of constant H , ϕ , and Ψ :

$$\begin{aligned} W &= H(\phi) \Delta P^2 Q \\ &= H(\phi) \frac{\pi^4 \Psi^2 \rho_0^2 D^4 N^4}{4} \frac{\phi \pi^2 D^3 N}{4} \\ &= \frac{\pi^6 \Psi^2 \rho_0^2 \phi H(\phi)}{16} (D^7 N^5) \sim D^7 N^5 \\ &\sim D^2 u_{\text{tip}}^5 \end{aligned} \quad (9)$$

because $u_{\text{tip}} = \pi N D$. The overall sound power at a constant point of operation increases as the square of the fan diameter and the fifth power of the rotor tip speed. For a well-designed quiet fan, the static efficiency of the fan will peak in the same range of Q

Figure 12 Noise spectra measured on a forward-curved centrifugal blower, where the static pressure rise is the variable.

where the specific sound power level is at its lowest. Equation (8) is perhaps one of the simplest empirical fan noise formulas to be found. It predicts the *trends* in overall sound power with fan speed and fan diameter. It does not distinguish fan type, but it *does* have its usefulness in noise control engineering.

Example Consider a fan of diameter 0.3 m operating at 3400 rpm. Equation (9) can be used to find either a new diameter or new operating speed that affects a 10-dB noise reduction while maintaining the same flow and pressure coefficient. The equation states that $W = D^7 N^5$. At constant rpm, we have

$$\begin{aligned} \frac{W_1}{W} &= \frac{D_1^7 N_1^5}{D^7 N^5} \Rightarrow 10 \log_{10} \left(\frac{D_1}{D} \right)^7 \\ &= -10 \Rightarrow D_1 = 0.72 D \end{aligned}$$

At constant diameter, we have

$$\begin{aligned} \frac{W_1}{W} &= \frac{D_1^7 N_1^5}{D^7 N^5} \Rightarrow 10 \log_{10} \left(\frac{N_1}{N} \right)^5 \\ &= -10 \Rightarrow N_1 = 0.63 N \end{aligned}$$

Thus, we could change the diameter to 0.22 m or change the fan speed to 2142 rpm to obtain a 10-dB overall noise reduction while maintaining the same value of ϕ and Ψ , which are nondimensional. The performance of the fan will suffer because of the noise reduction changes imposed. Equations (2b) and (3) indicate that at constant speed, the flow rate is proportional to D^3 and the pressure rise

to D^2 . The new flow would be $Q_1 = 0.37 Q$ and the new pressure rise would be $\Delta P_1 = 0.52 \Delta P$. At constant diameter, these new values are $Q_1 = 0.63 Q$ and $\Delta P_1 = 0.40 \Delta P$. One needs to decide from the application whether these decreases in performance can be justified. If flow rate is more important than pressure rise, then one might choose to lower the fan speed to obtain the 10-dB noise reduction, rather than the diameter.

5.1 Sound Power Spectrum of the Noise

Based on the research of Graham and Hoover⁹ and others, Table 1 gives specific sound power levels in several octave bands for a variety of fans. These levels are given in decibels with the reference quantities: $W_{\text{ref}} = 10^{-12} W$, $Q_{\text{ref}} = 1 \text{ m}^3/\text{s}$, and $\Delta P_{\text{ref}} = 1 \text{ kPa}$. We use the first of Eq. (9) to predict the octave-band sound power spectrum (L_W vs. octave band center frequency) of a given fan operating at nonreference values of Q and ΔP . Simply add $10 \log_{10} Q + 20 \log_{10} \Delta P$ to the tabulated levels. In the octave band where the BPF [Eq. (5)] lies, add to that level the increment given in the last column of the table. The sound powers computed by this approach include both fan inlet and fan outlet noise. Subtract 3 dB from the octave band levels if either inlet or outlet noise alone is desired.

6 OTHER EMPIRICAL METHODS FOR BROADBAND FAN NOISE PREDICTION

Although the specific sound power level method is widely used to make engineering estimates of the sound power radiated by typical commercial fans, there are other methods found in the fan noise literature that include additional details of the fan performance or geometry. We begin with one of the earliest.

Table 1 Specific Sound Power Levels in Eight Lowest Octave Bands for a Variety of Axial and Centrifugal Fans

Fan Type	Rotor Diameter (m)	Octave Band Center Frequency (Hz)								Add for BPF

6.1 Centrifugal Blower Sound Power–Shaft Power Correlation

Realizing that acoustic efficiency (η) is sound power divided by the mechanical power that drives the source, Beranek et al.¹⁰ developed empirical noise formulations based on shaft horsepower of the fan. The sound power radiation from a wide class of blowers (where $\eta = 10^{-6}$) operating in the ducts of building ventilation systems formed the foundation of this investigation. The authors measured the sound power spectrum from 14 different blowers operating in several different systems. The overall sound power measured in these experiments correlated to

$$L_W = 90 + 10 \log_{10} \text{SHP re } 10^{-12} \text{ W} \quad (10)$$

where SHP is the shaft power of the blower in horsepower. The measured data for the group of fans used in this study yield a spread of about ± 4 dB about the line computed from Eq. (10). The octave band sound power spectrum was found to slope off with increasing frequency at a rate of 5 dB per octave. The level of the first band, centered at 20 Hz, is 1 dB below the overall level predicted by Eq. (10).

6.2 Power Spectrum of Forward-Curved Centrifugal Blower Noise

Maling¹¹ expanded the empirical relation of Beranek et al.¹⁰ to include the effects of diameter, blower width, blower speed, pressure rise, volumetric flow rate, flow coefficient, and Mach number. He arrived at empirical formulas for the narrow-band radiated sound power spectra based on measurements from a set of three groupings of geometrically similar forward-curved centrifugal blowers. All of the blowers had 28 blades. The widths and diameters varied from group to

group, but the width-to-diameter ratio remained fixed at 0.5. Maling defines the following nondimensional parameters:

$$\theta = E / \rho_0 c_0^3 D^2 \quad (E = \text{sound power/Hz})$$

$$M = \pi D N / c_0 \quad (\text{rotor tip speed Mach number})$$

$$\phi = 4Q / \pi^2 D^3 N \quad (\text{flow coefficient})$$

$$s = f / N \quad (\text{frequency parameter})$$

$$\text{Re} = \pi N D^2 / \nu \quad (\text{Reynolds number based on } u_{\text{tip}})$$

where ρ_0 = density of air (kg/m^3), and ν = kinematic viscosity of air (m^2/s). He also suggests that $\theta = F(M, \phi, s)$, so that the overall sound power is

$$W = \int_0^\infty E(f) df = \rho_0 c_0^3 D^2 F(M, \phi) \quad (11)$$

The experiments were performed in a special duct facility designed for the purpose. Maling's measurements of the blower sound power at different Mach numbers helped to define a new θ function given by $\theta = M^3 g(s, \phi)$. The sound power spectral relations become

$$\begin{aligned} E &= \rho_0 c_0^2 D^3 M^3 g(s, \phi) \\ &= \rho_0 c_0^2 D^3 M^3 g_0(s) h(\phi) \end{aligned} \quad (12)$$

It was shown that the dependence on ϕ is quite weak, and $h(\phi) \simeq 1$. Collectively, the measured data appear to correlate to within ± 4 dB of

$$g_0(s) = (f/N)^{-2.67} \quad (13)$$

The final empirical result for the sound power spectrum (per hertz) radiated by small forward-curved centrifugal blowers is

$$E = \rho_0 c_0^2 D^3 M^3 (f/N)^{-2.67} \quad (14)$$

From this relationship, the overall mean-square sound pressure scales like $p^2 \sim D^{0.4} u_{\text{tip}}^{5.67}$.

6.3 Axial Fan Broadband Noise Prediction

While the Beranek et al.¹⁰ and Maling¹¹ methods help to predict broadband noise from centrifugal fans, Wright¹² addressed the broadband noise of axial fans. He measured the sound power from a variety of fans and correlated the data to the important flow and geometrical parameters. Considered are rotor-only propeller fans (R), fans with a rotor and outlet guide vanes (R-O), and fans with both inlet and outlet guide vanes straddling the rotor (I-R-O). Wright found that the measured power levels correlate well with a newly introduced *peak velocity* parameter. This velocity is the maximum surface velocity that exists on the rotor blades. It depends strongly on fan loading as indicated by the following expression:

$$V_p = K u_{\text{tip}} \left(\sqrt{1 + \phi^2} + \frac{\Psi b}{4C\eta_s} \right) \quad (15)$$

where C is the blade chord at the tip, and b the blade spacing. The factor K is related to the flow through the fan according to

$$\begin{aligned} K &= 1 + 1.64|\hat{Q}|^{3/2} \quad \hat{Q} < 0 \\ &= 1 + 0.5|\hat{Q}|^{3/2} \quad \hat{Q} > 0 \end{aligned} \quad (16)$$

where $\hat{Q} = (Q - Q_d)/|Q_s - Q_d|$. Here, subscript d stands for *design* value and subscript s indicates the *stall* value. Empirical formulas that predict overall sound power, within ± 3 dB of measured data, for each of the three types of fans are

$$\begin{aligned} L_w &= 53.4 \log_{10} V_p - 25.7 \quad \text{I-R-O} \\ &= 50.9 \log_{10} V_p - 28.1 \quad \text{R-O} \\ &= 38.2 \log_{10} V_p - 6.1 \quad \text{R} \end{aligned} \quad (17)$$

6.4 Turbulence Ingestion Noise

Turbulence ingestion noise results when turbulence is ingested into either axial-flow or centrifugal fans; it is a low-frequency, broadband noise. This noise is due to the turbulence interacting with the rotor blade leading edges causing unsteady lift, which results in direct dipole sound radiation according to Eq. (6). Figure 13 shows a schematic of the situation. Two time scales exist, one associated with the turbulence and the other associated with the rotor. When $t_{\text{turbulence}} \ll t_{\text{rotor}}$, or

Figure 13 Interaction of free-stream turbulence of axial length scale Λ_x interacting with a rotor blade row moving at circumferential velocity ΩR .

when $\Lambda_x \ll b$ (because $W_{\text{rel}} \simeq U$), the unsteady rotor force spectrum is broadband with a continuous roll-off as the frequency increases. When these time scales become comparable, meaning that the turbulence scale becomes equal to or greater than the blade spacing, blade-to-blade correlation exists in the rotor force distribution. In other words, more than one blade interacts with a given turbulent eddy at a given instant. Then, broad humps, centered about the harmonics of the BPF appear in the unsteady rotor force and radiated noise spectrum. The large eddies behave like quasi-time-invariant inflow distortions. Such flows are common in fans operating near boundaries and behind grids, such as automotive engine cooling fans; for example, see Mani,¹³ Mellin,¹⁴ and Mugridge.¹⁵ The theory for predicting fan rotor unsteady force spectra and noise due to turbulence ingestion is complicated and beyond the scope of this chapter. Please see Blake¹⁶ and Howe¹⁷ for the theoretical approaches.

7 DISCRETE-FREQUENCY FAN NOISE PREDICTION

7.1 Tonal Noise from Blowers

Blade pass frequency tones occur in centrifugal blowers, particularly when they are operated off-design. The major source of these tones is the interaction of the impeller blade trailing edges with the cutoff. Neise¹⁸ used a spectral decomposition technique to separate a fan-radiated noise spectrum into independent functions that are multiplied together. One function depends on Helmholtz number D/λ and describes the acoustics of the system in which the fan is operated. The second is the fan aerodynamic source function that depends on Strouhal number and describes the aerodynamically induced sound generated by the fan. The Strouhal number defined by Neise is

$$\text{St} = \frac{f D}{u_{\text{tip}}} \frac{\pi}{B}$$

Table 2 Aerodynamic Source Function of Eq. (18) Measured and Compiled by Neise¹⁸ for Three Different Centrifugal Blowers Radiating Sound at the Indicated Harmonics of the BPF^a

Strouhal Number $St = \frac{\pi f D}{B u_{tip}}$	Aerodynamic Source Function $20 \log_{10} F(St) \text{ (dB)}$
1	143.0
2	136.5
3	133.5
4	132.5
5	131.0
6	129.0

^a The uncertainty in these data is ± 2 dB

It is seen to equal 1, 2, 3, ... at each of the respective harmonics of the blade pass frequency. The aerodynamic source function, tabulated in Table 2, is given by

$$F(St) = \frac{p(St)/p_0}{M^\alpha R e^\beta} \quad (18)$$

with constants $\alpha \approx 2.1$, $\beta \approx 0.2$, and $p_0 = 20 \mu\text{Pa}$. The parameters of this equation are the same as those preceding Eq. (11). The mean-square sound pressure radiated at the harmonics of the blade pass frequency follow $\overline{p^2}(St) = u_{tip}^{6.2} D^{0.4}$, which shows a lesser dependence on diameter than the Madison law⁸ but agrees well with the Maling¹¹ results.

7.2 Theory of Interaction Noise in Axial Fans

Detailed derivations of the discrete-frequency components observed in the unsteady force and radiated noise spectrum of axial-flow devices may be found in many different research studies; Blake¹⁶ provides a complete summary of these. Interaction noise theory assumes that a rotor is exposed to a time-invariant, spatially nonuniform inflow velocity field. The essence of the theory is the development of a Green's function that describes the field at \mathbf{x} due to a simple rotating source (or force) at \mathbf{y} :

$$G(\mathbf{x}; \mathbf{y}, \omega') = \sum_{n=-\infty}^{\infty} \frac{e^{ik_0 r}}{4\pi r} J_n(k_0 R \sin \beta) \times e^{in(\theta - \theta_0 - \pi/2)} \delta(\omega' - \omega + n\Omega) \quad (19)$$

Figure 14 provides a definition of the symbols used in this function, and J_n is the Bessel function of the first kind and order n . If the rotating source at radius R is a time-periodic source of frequency ω_0 , then the radiated sound pressure spectrum is given by

$$\Phi_{\text{rad}}(\omega) = \frac{1}{16\pi^2 r^2} \sum_{n=0}^{\infty} \Phi_d(\omega_0 \pm n\Omega) \times \left| J_n \left(\frac{\omega_0 \pm n\Omega}{c_0} \right) R \sin \beta \right|^2 \times \delta(\omega - \omega_0 \pm n\Omega) \quad (20)$$

Figure 14 Definition of variables used for analyzing the radiation from a rotating force F_i or acoustic source at radius R .

where $\Phi_d(\omega)$ is the *discrete* pressure spectrum of the source. This, for example, may be due to the impulsive loading at each radial position of a blade that periodically intersects the wake of a fixed obstruction like an upstream guide vane. Even though the source is periodic at ω_0 , the field contains an infinite number of sideband frequencies at integer multiples of the source rotation rate Ω . These are a result of Doppler effects. The term in Eq. (20) that contains the Bessel function is called the *Bessel envelope*. It is a curve that envelopes the magnitudes of all of the tones in the radiation spectrum. These discrete tones are $\omega_n = \omega_0 \pm n\Omega$. Note that the Bessel envelope changes shape with the value of the observation angle β .

Now if the rotating source (or force) has a nondiscrete *continuous* spectrum $\Phi_c(\omega)$, then the radiated noise spectrum is simply

$$\Phi_{\text{rad}}(\omega) = \frac{\Phi_c(\omega)}{16\pi^2 r^2} \quad (21)$$

A broadband rotating source is unaffected by Doppler effects and its sound spectrum is proportional to the source spectrum. This is the situation for radiation from rotor trailing edges, blade surface turbulent boundary layers, and localized blade flow separation zones.

Rotor-stator interactions cause many tones to appear in the spectrum of fans with inlet and/or outlet guide vanes. Figure 15 describes the problem. The radiated sound pressure Fourier component is composed of the contributions from many modal pressure patterns:

$$P(\mathbf{x}, \omega) = \sum_{m=-\infty}^{\infty} \sum_{w=-\infty}^{\infty} P_{w,m}(\mathbf{x}, \omega) \quad (22)$$

where

$$P_{w,m}(\mathbf{x}, \omega) = -\frac{iB}{4\pi r} \left(f_{1,w} k_0 \cos \beta + \frac{mB - w}{0.7R_t} f_{\theta,w} \right) \times J_{mB-w}(0.7k_0 R_t \sin \beta) \times e^{i[k_0 r + (mB-w)(\theta - \pi/2)]} \delta(\omega - mB\Omega) \quad (23)$$

Figure 15 Rotor–stator interaction noise occurs when the wakes of a fixed-blade row interact with the rotating blade row.

Equation (7) can be used to express the radiation spectrum based on these Fourier components.

The modal sums of Eq. (22) are over the harmonics of the BPF and over the harmonics of the circumferential wavenumber distribution of the stator wake perturbation. For a given blade section of chord length C , canted at the angle γ from the axial direction, the axial and circumferential lift per wake harmonic are given, respectively, by

$$f_{1,w} = \int_{R_h}^{R_t} L'_w \left(\frac{C}{R}, \frac{wC}{R} \right) \cos \gamma e^{i w \vartheta_w} dR \quad (24)$$

$$f_{\vartheta,w} = \int_{R_h}^{R_t} L'_w \left(\frac{C}{R}, \frac{wC}{R} \right) \sin \gamma e^{i w \vartheta_w} dR \quad (25)$$

The forces to be integrated represent *unsteady lift* and *unsteady drag* per unit span. They depend on the radial ($1/R$) and circumferential (w/R) wavenumbers as used in the two-dimensional Sears function¹⁹:

$$L'_w \left(\frac{C}{R}, \frac{wC}{R} \right) = \pi \rho C |V(R, w)| u(R) S_{2D} \left(\frac{C}{R}, \frac{wC}{R} \right) \quad (26)$$

where $|V(R, w)|$ is the magnitude of the circumferential wavenumber spectrum of the spatially nonuniform and time-invariant rotor inflow velocity profile. The two-dimensional Sears function is

$$S_{2D}(x, y) = S_e(x) \frac{1 + 3.2\sqrt{x}}{1 + 2.4y^2 + 3.2\sqrt{x}} \quad (27)$$

where

$$S_e(x) = \frac{2}{\pi x [H_0^{(1)}(x) + i H_1^{(1)}(x)]} \quad (27a)$$

is the one-dimensional Sears function, and $H_n^{(1)}(x) = J_n(x) + i Y_n(x)$ is the Hankel function of the first kind.

The wavenumber spectrum is determined from the measured or predicted rotor inflow field. Computational tools exist to predict the wake profile from upstream stator blade rows. Or, measurements can be performed with standard techniques such as laser-Doppler velocimetry, particle imaging, or scanned five-hole pressure probes. See Chiu et al.²⁰ for an example of the experimental approach. Essentially, the radially dependent circumferential variation of mean velocity in the wake of the stator is broken into Fourier components:

$$V(R, w) = \frac{1}{2\pi} \int_0^{2\pi} v(R, \vartheta) e^{-i w \vartheta} d\vartheta \quad (28)$$

$$v(R, \vartheta) = \sum_{w=-\infty}^{\infty} V(R, w) e^{i w \vartheta}$$

Examination of the modal pressure given by Eq. (23) reveals the following:

1. $\delta(\omega - mB\Omega) \Rightarrow$ sound is produced only at $\omega = mB\Omega$, the frequencies of radiation are multiples of the blade pass frequency.
2. $J_0 > J_n \Rightarrow n = mB - w = 0$ results in the highest magnitude modal pressure. The strongest axial forces and sound are produced when $w = mB$.

Example Consider a rotor–stator interaction where there are B rotor blades and V stator vanes. This relation means that when $nV = mB$ (where n and m are integers) there will be large axial forces. For example, if $B = 3$, and $V = 4$, we find $4B = 3V = 12$ is the lowest combination of integers that makes the equality. Since $m = 4$, the fourth harmonic of the BPF will radiate substantial sound. It can also be shown that for *minimum radiation* at the fundamental BPF, choose rotor–stator combinations such that

$$V_{\min} + \frac{V_{\min}}{B} = V_{\max} - \frac{V_{\max}}{B} \quad (28a)$$

If $B = 4$, Eq. (28a) suggests that the best number of stator vanes would be 3 or 5.

3. When $mB - w = 0$, the tangential forces contribute nothing to the modal pressure.
4. However, when $w = mB \pm 1$, the tangential (side) forces will be large. For rotor–stator interactions, large side forces exist when $nV = mB \pm 1$. For the case of $B = 3$ and $V = 4$, the side force (and vibration) will be large at the BPF.
5. When $w = 0$, the inflow is *steady* and *uniform*. The resulting noise, called *Gutin* noise, is from

the *steady-state thrust* of the rotor.²¹ Gutin noise is discrete at harmonics of the shaft rate, and it is important only when $M_{\text{tip}} = u_{\text{tip}}/c_0 \rightarrow 1$.

6. In the time domain, the delta function returns to $e^{-imB\Omega t}$. Couple this with $e^{i(mB-w)\theta}$ to get $e^{-i(mB\Omega t - mB\theta + w\theta)}$. On a constant phase trajectory (wavefront) $n\theta \equiv mB\theta - w\theta = mB\Omega t$ from which $d\theta/dt = mB\Omega/n$. This angular velocity of the phase trajectory implies that the mode n is "spinning." There will be some higher-order spinning modes that have modal tip speeds greater than the sonic velocity, $\theta R_t \geq c_0$. These pressure components will propagate to great distances.

7.3 Other Sources of Tonal Noise in Fans

Thickness noise, like Gutin noise, is a high Mach number source of sound that is not normally encountered in low-speed fans. It is a monopole (volume) source caused by the dynamical displacement of fluid as a blade of nontrivial thickness cuts through it. Thickness noise is one source of helicopter rotor noise.

In the complex fields of fluid-structure and fluid-acoustic interactions, a situation called *locking-in* is defined when one unsteady characteristic of a process reinforces a similar characteristic in another process (and vice versa) such that a feedback loop forms causing the common characteristic of both processes to be amplified. Several examples of lock-in are covered in Howe¹⁷ and in Lucas et al.²² and some of them occur in fans.

Mechanical resonances of fan rotor blades, vanes, and other components can be excited by fluid flow. These events may produce additional fan noise tones. One common lock-in phenomenon for fan blades is *singing*. This happens when the frequency of a resonant flexural mode of blade vibration matches the frequency of vortex shedding from that blade. The acoustic tone generated is not situated at any particular harmonic of the shaft rate frequency, but it is at the mechanical resonance frequency of the vibratory mode.

A more complex form of lock-in that can occur in low-speed fans is called *laminar boundary layer-wake interaction*. Qualitatively speaking, periodic shear layer velocity perturbations, due to Tollmein-Schlichting waves and hairpin vortices, occur during transition from laminar-to-turbulent boundary layer flow on rotor blades when the Reynolds number based on chord length is in the approximate range $10^5 < UC/\nu < 10^6$, where U is the velocity at the leading edge of the blade. If the frequency of these periodic shear layer instabilities matches the frequency of vortex shedding, then a hydrodynamic lock-in phenomenon takes place. This causes the periodicity in the wake of the blade to be amplified. If these vortex frequencies happen to be near a harmonic of the BPF, then significant increases in the sound at this frequency will occur. Turbomachinery designers try to design rotor and stator blades that operate at

chord Reynolds numbers in excess of a million. That assures that the boundary layers are turbulent and free of organized vortex structures that can lead to lock-in problems. It further assures that the performance of the fan does not become unstable under certain flow conditions within the operating envelope. This instability problem has been encountered with small, subsonic cooling fans in the range of Q corresponding to the peak in static efficiency.²³

8 NOISE CONTROL FOR FANS AND BLOWERS

The specific sound power levels given in Table 1 are based on fans operating at or very near their peak (static) efficiency point. As previously mentioned, minimum noise from a well-designed fan occurs when it is operated in this range. The notable exception is for small cooling fans that may be unstable in this range. Therefore, one must be cautious in attempting to lower noise by adjusting fan speed or size based on Eqs. (8) and (9). This was demonstrated by the example following those equations.

Caution must also be exercised when modifying an already well-designed fan for noise control purposes. Some noise reduction may be achieved, but more than likely, the fan performance will be degraded along the way. Nevertheless, over the many decades of fan design and fan noise research, there have been some successes at lowering fan noise through component redesign or modification without serious degradation of performance. A few of those methods are highlighted.

Embleton²⁴ studied various methods to reduce centrifugal blower noise, particularly noise radiating at the BPF:

1. Increasing the impeller-to-cutoff distance lowered BPF noise. Figure 16 shows that there is an optimum distance of approximately $0.018D$ that should exist between the impeller trailing edge and the volute cutoff for minimum noise.

2. Increasing the radius of the cutoff tends to reduce the impulsive pressure created by the rotating blades; thus, the practice is a proven noise reducer.

3. Skewing or spiraling the impeller blades relative to the cutoff is a relatively expensive manufacturing option that can significantly reduce BPF noise. The technique is also used in laying out knife patterns on the cutterheads of planers and joiners used in the woodworking industry.

4. Staggering the blade rows in double-row impellers can also help to reduce BPF noise.

5. Mismatching the acoustic impedance of a fan inlet (and outlet) from that of the connecting ductwork is a passive means of attenuating fan noise (see also Chapter 57). For an axial fan, this can easily be accomplished by placing relatively short sections of lined pipe up and downstream of the fan. The sound-absorbing material that makes up the liner attaches to the inside of the pipe. Choose a liner that has a protective covering so that particulates of the absorbing material are not swept away by the airflow. Because the fan is a dipole source, be sure that the length of

Figure 16 Effect of cutoff distance on overall sound pressure level, OASPL, and on volumetric flow rate, Q , of centrifugal blower. (From Embleton.²⁴) ft^3/min (cfm) $= 0.472 \times 10^{-3} \text{ m}^3/\text{s}$.

the lined sections of pipe are not an integer multiple of a half wavelength of sound at the BPF, or at other frequencies of concern.²⁵ In the case of blowers, a dissipative muffler can be added at both inlet and outlet. Such mufflers that do not affect the airflow are commercially available.

6. Use tuned resonators for controlling tones. A tuned resonator for a blower might consist of a cavity mounted behind the cutoff. Screen or perforated plate separates the cavity from the moving air in the cutoff region. For axial fans, the cavity can be integrated into the hub. The cavity is designed to have rigid walls and to be a one-quarter wavelength ($\lambda/4$) long at the BPF. This wavelength is $\lambda = c_0/\text{BPF}$. The application of this method to a centrifugal blower was demonstrated by Neise and Koopmann.²⁶ Figure 17 shows a sketch of a cutoff-mounted resonator. Figure 18 shows acoustic data measured by the author on the same blower of Fig. 12 with a one-quarter wavelength resonator installed in the cutoff.

7. Unequal rotor and/or stator blade spacing is a technique that shifts the high-level sound energy that is in the few harmonics of the BPF to the many more harmonics of the shaft rate frequency. It generally does not change the overall sound power because the original sound energy is simply redistributed into different (and many more) frequency bands. The sound

Figure 17 Sketch of a quarter wavelength resonator for blower BPF noise control.

Figure 18 Sound pressure level spectra measured for a forward-curved centrifugal blower at different speeds. A cavity resonator is mounted in the cutoff of the volute. When the length of the cavity corresponds to the one-quarter wavelength at the frequency of the BPF, tonal noise reduction is observed. The frequencies in parentheses are the BPF's for the noted rotor speed.

pressure spectrum has fewer high-level tones and many more lower-level tones. The spectrum is essentially "whitened." Arranging the rotor and stator blades in a circumferential unequal pattern is a *sound quality control* technique rather than a noise control technique.

Mellin and Sovran²⁷ provide tables of blade spacing for optimum suppression of the strongest blade rate harmonic, based on the number of blades and whether or not the configuration is dynamically balanced. For a given circumferential pattern of rotor and stator blades, strong interaction occurs because of the cumulative effect of one discontinuity passing by all of the others set up by the stationary blade row. Frederick and Lauchle²⁸ show that this is a cross-correlation function $R_{AW}(\Delta\theta)$ that is formed between

the rotor circumferential blade pattern and the stator circumferential vane pattern. Fourier transforming the cross-correlation function yields a cross spectrum $S_{AW}(m)$ for the orders of shaft rate that will dominate the noise spectrum. In particular,

$$R_{AW}(\Delta\theta) = \frac{1}{2\pi} \int_0^{2\pi} W(\theta)A(\theta + \Delta\theta) d\theta \quad (29)$$

$$S_{AW}(m) = \int_0^{2\pi} R_{AW}(\Delta\theta) e^{-im\Delta\theta} d\Delta\theta \quad (30)$$

Figure 19 shows an example wake and rotor spacing pattern along with the resulting interaction spectrum. The method yields the frequencies and relative magnitudes of the radiation tones that will be generated from unequal blade spacing. Practical examples of the method may be found in Frederick and Lauchle²⁸ and in Brungart and Lauchle.²⁹ The technique can also be used to design acoustically pleasing tire tread patterns.

8. Trailing-edge modifications can reduce broadband noise. The acoustic pressure spectrum of trailing-edge noise is proportional to the product of the spectrum of the local wall pressure fluctuations that occur near the trailing edge and to the spanwise correlation length of these pressure fluctuations. The correlation length is the average (statistically speaking) distance over which a pressure-producing eddy remains correlated with itself. Typically, this length is some fraction of the turbulent boundary layer thickness at the

trailing edge. The largest correlation lengths—and noise—occur when the flow leaves the surface at right angles to the span, as it does, say in plenum impellers (Fig. 6). Roughening the trailing edge with applied sandpaper decorrelates the pressure fluctuations but raises the level of the local wall pressures; thus, such a measure is not usually effective in reducing overall noise. Serration of the trailing edge, on the other hand, does little to the local wall pressure fluctuations, but it can reduce the correlation lengths. Howe¹⁷ analyzes the noise reduction due to serrations of sinusoidal shape and of sawtooth shape. The sawtooth pattern yields larger noise reductions than the sinusoidal edge pattern. When a sawtooth serration of peak-to-peak amplitude $2h$ and period λ_{edge} is added to a blade trailing edge, Howe shows that the attenuation in decibels is $10 \log_{10}[1 + (4h/\lambda_{\text{edge}})^2]$. The angle that the sawtooth makes with the free-stream velocity vector should be less than 45° and $h = \delta$ for effective noise reduction, where δ is the boundary layer thickness at the trailing edge. Choosing $h/\lambda_{\text{edge}} = 1$ results in 12.3 dB trailing-edge noise reduction.

9. Active control is a technique that has shown some success in reducing tonal noise from fans. Two approaches are possible: create antisound from a speaker, or an array of speakers, placed near the fan,^{30–32} or create antiferce with a mechanical shaker that is presumed to cancel the unsteady aerodynamic forces created by the fan.³³ Both approaches utilize the feedforward, filtered-x, least-mean-square adaptive noise control algorithm³⁴ that requires a fan blade rotational sensor, like a tachometer. Both approaches are effective in reducing the lower-order blade pass frequency tonal noise. Sound pressure level reduction of the BPF noise has been shown to be as high as 22 dB, while global sound power reductions of up to 14 dB have been demonstrated. Reduction of broadband fan noise by active means is still in a developmental stage.

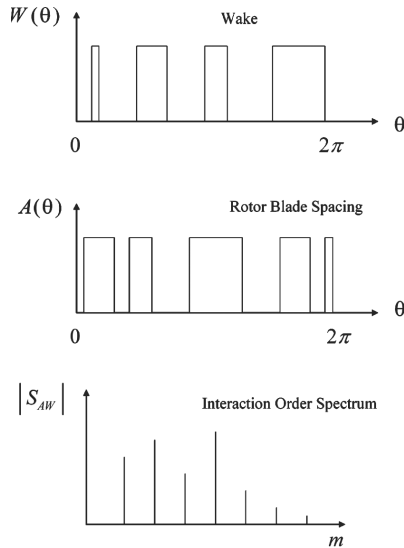

Figure 19 In analyzing the tones that are created in an unequally spaced rotor–stator combination, the positions of the rotor blades and interacting stator wakes are plotted circumferentially as unit step functions. The interaction order spectrum is the cross spectrum between these two circumferential patterns. It shows those multiples of the shaft rate frequency where tones will occur in the fan noise spectrum.

CHAPTER 72

TYPES OF ELECTRIC MOTORS AND NOISE AND VIBRATION PREDICTION AND CONTROL METHODS

George Zusman
IMI Sensors Division
PCB Piezotronics
Depew, New York

1 INTRODUCTION

Electric motors, or machines, are used to convert electrical energy into mechanical energy and may be subdivided into asynchronous, synchronous, and direct current (dc) machines. The sources of noise and vibration in electric machines are the following: electromagnetic forces, bearings, aerodynamic forces, imbalance, and rubbing. Electromagnetic forces are active in the air gap between the stator and the rotor and are characterized by rotating or pulsating power waves. In most types of electric machines, the magnetic vibration is in the range of 100 to 4000 Hz. The intensity of the vibration and noise in bearings is determined by the quality of manufacture, the accuracy of machining of the bearing seats, and the vibroacoustic properties of the end brackets.

Noise based on aerodynamic forces depends on the construction of the fan and ventilation channels of the machine. Mechanical imbalance of rotors may excite an appreciable amount of vibration, particularly in high-speed machines. The rubbing of brushes against the commutator or contact rings is predominantly a high-frequency source of noise. Vibration and noise prediction and control methods of electromagnetic origin are based on the diagnostics of electrical motor defects using spectrum analysis of the vibration signals.

2 OSCILLATORY FORCES OF ELECTROMAGNETIC ORIGIN

The vibration of electromagnetic origin in electric machines may have several different components. They are mainly concerned with electrodynamic, electromagnetic, and magnetostrictive oscillatory forces.

The electromagnetic forces acting in the defect-free electric machine have radial direction and angular symmetry. Therefore, in the defect-free machine the sum of electromagnetic forces acting on the rotor is equal to zero. The stator is affected by the electromagnetic forces that tend to deform it, the spatial shape of these forces being a circular wave characterized by a number of waves r appearing on the circumference of the stator. The value r is called the order of stator oscillations. The mechanical rigidity of the stator grows fast with the growth of the oscillations order; therefore, during analysis of vibrations only deformations on low orders are taken into consideration.¹

The greatest oscillations of the stator of a defect-free alternating current (ac) machine excited by electromagnetic forces from the main magnetic field wave happen in electric machines with alternating current with one pair of poles $p = 1$. In such machines the stator deformation is of second order $r = 2$, and the body oscillation amplitude on the doubled feed voltage frequency is about 10 mm/s. In case of asymmetric clearance, first-order oscillatory forces appear, and the vibration of the machine may grow sharply.

The electrodynamic forces in the electric machine are arbitrarily called electrodynamic since the windings are in the slots and the magnetic field does not cross the conductors with current. Actually, the windings of the stator and rotor create their own electromagnetic fields in the machine clearance rotating with one speed and shifted in the circle with respect to one another for a certain displacement angle θ . These fields tend to compensate one another to create a working moment of the machine. Naturally, in a defect-free machine, the mechanical forces act not on the conductors but on the teeth of the rotor (stator).

However, for the magnetic saturation of the tooth zone the oscillatory forces start acting directly on the windings, which sharply decreases their reliability and service life. In real electric machines both the current in the rotor (armature) or stator windings and the electromagnetic field created by them contain not one but many harmonic components of various frequencies and amplitudes. Many of these components appear or essentially change in the presence of defects in the electromagnetic system of the electric machine.

In a defect-free electric machine supplied with ideal-shaped voltage, the additional variable components of the magnetic field and current appear due to:

- Discrete distribution of windings in several slots causing a nonsmooth shape of the magnetomotive force created by the windings
- Irregularities of the air gap due to the presence of teeth or apparent poles in the active armature bringing about the appearance of magnetic conductance components Λ (as per the circular coordinate v)

With the appearance of defects in the electromagnetic system of the electric machine the number of components of the oscillatory forces of electromagnetic nature may grow due to:

- Asymmetry of the air gap, partially the static eccentricity of the gap caused by the displacement of the stator axis with respect to the rotor rotation axis, or the dynamic eccentricity of the gap caused by displacement of the rotor geometric axis with respect to its rotation axis
- Magnetic saturation of separate tooth zones of the rotor (armature) or stator
- Defects either in the windings of the rotor or stator, or their active armatures causing asymmetry of magnetic fields
- Appearance of armature current pulsations in the dc machine due to defects in the brush-commutator assembly or armature windings, as well as pulsations of the field current in dc machines or synchronous ac machines

The causes of changing of parameters of the electromagnetic field in the air gap and other parts of electric machines (in addition to the above-mentioned defects) may be looseness of active armature packets, defects of end windings, asymmetry, or nonlinear distortions of the electric machine supply voltage.²

The analysis of oscillatory forces and vibrations of electromagnetic origin emerging in the electromagnetic system of an electric machine, as a rule, make it possible to detect possible defects in the machine or distortions in the electric line supply voltage. Vibration diagnostics pays more attention to the pulsating moments that change greatly with appearance of defects that to the radial electromagnetic forces calculated in the process of machine designing and controlled within the framework of its postmanufacture outgoing inspection. This approach to electric machine vibration diagnostics offers certain advantages compared with machine diagnostics performed by spectral components of the consumed current.^{2,3}

3 VIBRATION DIAGNOSTICS OF ASYNCHRONOUS ELECTRIC MOTORS

In asynchronous electric motors the number of various-frequency vibration components of electromagnetic nature is much more than in synchronous electric machines or dc machines. This is explained by a small value of the air gap δ and slippage of the rotor with respect to the rotating magnetic field of the stator. The magnetic field of the asynchronous electric motor is characterized by two main frequencies, namely the supply voltage angular frequency ω_1 and the magnetic field main spatial wave rotational frequency Ω_1 determined by the circular velocity of motion of this wave $\Omega_1 = \omega_1/p$, where p is the number of pole pairs.

Rotor rotation is characterized by a somewhat lower frequency $\omega_{rt} = \Omega_1(1 - S) = \omega_1/p(1 - S)$, where S is the rotor slippage, which is usually within the range of $0.01 < S < 0.05$. With the growth of load

in the asynchronous electric motor, the rotor slippage frequency and the current induced in it change, while the amplitude of the main magnetic field remains practically the same. The value of the clearance in an asynchronous electric motor depends on its size and the number of pole pairs, diminishing from the value of 2 mm in two-pole machines with power over 500 kW to 0.2 mm in multipolar machines of low power.⁴

The "toothedness" of the stator leads to the fact that the magnetomotive force of the stator in addition to the main harmonic with a frequency of the supply mains voltage contains a number of higher harmonics, and the magnetomotive force induced in the rotor, in addition to the main harmonic has a number of higher harmonics determined by the toothedness of the rotor. The harmonics of the magnetomotive force of the rotor and stator create corresponding magnetic field components in the clearance; these components, in their turn, are sources of electromagnetic radial oscillatory forces. The same components of the magnetic field, by interacting with the currents existing in the stator and rotor windings, create tangential electrodynamic constant and oscillatory forces (moments of forces). The peculiarity of the action of the oscillatory forces is their wave character. In defect-free asynchronous electric motors, by integrating over the surface of the rotor, the oscillatory forces (radial and tangential) are reduced, while the overall oscillatory forces acting on the rotor are equal to zero. The same holds true for the tangential electrodynamic forces acting on the stator. The low-order electromagnetic radial oscillatory forces tend to flex the stator, which can be represented in the form of a thick-walled cylindrical casing, by creating a wave of radial oscillations of doubled frequency and doubled spatial order.

The number of components of asynchronous electric motor vibration excited by radial electromagnetic forces is large even in the absence of defects in the machine and on the condition that it is fed from the mains with an ideal voltage. At the same time, the main contribution to vibration of defect-free asynchronous electric motors is made by several electromagnetic components with frequencies equal to the double supply voltage frequency and toothed frequencies. These vibration components are usually controlled at the design development stage and during outgoing inspection (after manufacture or major overhaul) of vibration characteristics of the machine.¹ These vibration components are noticed in machines having defects in the electromagnetic system and, first of all, in machines with asymmetry of the air gap; namely its fixed (static eccentricity) and rotating (dynamic eccentricity) asymmetry. Only in the last few years has it become possible to take account of possible changes of vibration of asynchronous electric motors due to pulsating oscillatory forces and moments appearing when the asynchronous electric motor is supplied with an asymmetric or nonsinusoidal voltage.² It is associated first of all with the use of static frequency converters of the supply voltage used in drives with variable speed control.

Many such converters do not ensure high-quality voltage signal at the output, thus increasing vibration of the asynchronous electric motor.

The vibration spectrum of the electromagnetic system of an asynchronous electric motor is in fact richer with the presence of various defects in it and is saturated with a great number of weak components excited first of all by tangential electrodynamic forces. The spectrum analysis of the components of asynchronous electric motor vibration makes it possible to detect and identify a large group of defects of the electromagnetic system. Radial components of vibration of an asynchronous electric motor stator may change greatly with the appearance of defects, particularly in case of eccentricities of the air gap. These changes happen first of all due to the reduction of the spatial order of oscillations on frequency $2\omega_1$ and toothed frequencies, as well as due to the appearance of electromagnetic forces with a frequency equal to the rotor rotation. These forces act between the rotor and stator and prevent essential reduction of asynchronous electric motor vibration achieved by balancing the rotor in proper supports.^{1,2}

In asynchronous electric motors operating often in the start mode, the strongest tooth component of vibration is usually the component with a frequency of $\omega_{z2} = \omega_z + 2\omega_1$, and for stable operation in one selected mode dominating tooth vibration frequency is $\omega_z - 2\omega_1$.

Taking into consideration that the mechanical resistance of the stator and the body of the asynchronous electric motor represented by a thick-walled cylindrical casing on high frequencies is much less, the toothed components of vibration may be very essential and determine to a large extent the vibration, particularly the air noise of the asynchronous electric motor.

To reduce the toothed components of the asynchronous electric motor vibration the slots are beveled. Usually beveling of slots is done on the rotor for one slot section, which helps reduce magnetic components of vibration of the motor three to five times.¹ The description of the electromagnetic vibration components in an asynchronous electric motor is coupled with the evaluation of the influence of defects, first of all, the asymmetry of the air gap, on the radial vibration of the machine.

In technical specifications for certain types of asynchronous electric motors, the limit values of admissible eccentricities of both types of the first spatial order are usually of the order of 10%, though in practice any type of eccentricity may reach magnitudes of the order of 50% and even higher, mainly due to the wear of bearings or the deformation of the stator as a result of errors when rigidly fastening the asynchronous electric motor to the foundation.

Due to static eccentricity in the clearance, additional components of the magnetic field appear with frequency ω_1 , including those having a lower spatial order. Due to dynamic eccentricity, there appear magnetic field components with frequencies $\omega_1 \pm k\omega_{\pi}$.

With static eccentricity, the maximum contribution to radial vibration is introduced by electromagnetic

forces of the first order with frequency $2\omega_1$, the amplitude of which in the first approximation is equal to the following:

$$F_{1st} \approx \frac{\varepsilon_{1st}}{2p\mu_0} B_0^2 \ell_{\pi} R_{\pi} \quad (1)$$

where ε_{1st} = relative eccentricity of the gap

B_0 = amplitude of flux density in a defect-free asynchronous electric motor

ℓ_{π} = length of the active portion of the rotor

R_{π} = radius of the rotor

p = number of poles

The amplitude of the excited frequency $2\omega_1$ of vibration of the test points on the end brackets or the body of the asynchronous electric motor is determined by the rigidity of the rotor and bearings (first critical frequency of the rotor), as well as by the rigidity of the end bracket and fastening assemblies used to secure the machine to the foundation. With great eccentricities of the gap ($\varepsilon > 0.1$) this vibration component may determine the low-frequency vibration of the asynchronous electric motor.

With dynamic eccentricity of the gap, the frequency of one of the components of radial electromagnetic forces determined by the interaction between the main and auxiliary waves of the magnetic field coincides with the rotor rotational frequency. The vibration excited by these forces may be less than the vibration of an asynchronous electric motor of frequency $2\omega_1$, since the mechanical resistance of the oscillatory system rotor-stator of frequency $2\omega_1$ may be much less than frequency ω_{π} . Nevertheless, it is exactly this component of electromagnetic force that determines the limit of reduction of asynchronous electric motor vibration at the rotational frequency in the process of balancing of the rotor on proper supports.

In addition to radial oscillatory forces of frequency ω_{π} , the dynamic eccentricity of the gap is a cause of radial components at oscillatory forces and vibration on frequencies of $2\omega_1 \pm \omega_{\pi}$ and essentially weaker components with frequencies of $2\omega_1 \pm k\omega_{\pi}$, $k > 1$.

The static eccentricity of the clearance may cause growth of toothed components of radial vibration of an asynchronous electric motor differing from the main toothed component by a frequency of $\pm 2\omega_j$, while the dynamic eccentricity may cause growth of toothed components of vibration differing by a frequency of $\pm j\omega_{\pi}$. It should be noted that greater changes of vibration of toothed frequencies with the eccentricity of the clearance may be caused by pulsating moments created by electrodynamic forces.

The next task of description of vibration is the determination of tangential oscillatory forces and pulsating moments in defect-free asynchronous electric motors operating from supply voltage mains with asymmetry and nonlinear distortions of the supply voltage.

The pulsating moment with frequency $2\omega_1$ depends not only on the amplitude of the field components and the current of forward and reverse succession, but also

on the difference of the corresponding initial phases of the field and current.

With electric asymmetry of the rotor winding (squirrel's cage), current additionally appears with a frequency $s\omega_1$ of having a direction of rotation opposite to that of the rotor.

It is quite difficult to calculate the pulsating moment of frequency $2s\omega_1$, and in case of the rupture of the rods in the squirrel's cage it may be evaluated only approximately.

As a rule, the frequency $2s\omega_1$ is quite low, that is, it may cause angular modulation of the rotational frequency of the asynchronous electric motor with a deviation of the rotational frequency quite sufficient for practical diagnostics. In the vibration spectrum of the asynchronous electric motor all harmonic components have side harmonics differing from the central frequency ω_r by values $2s\omega_1$.

The dynamic eccentricity of the air gap causes of a variable component of clearance conductivity with frequency ω_r and considerably lower (in amplitude) conductivity components with frequencies $k\omega_r$, where $k = 1, 2$.

Interaction of additional components of the flux density of the stator with the main wave of the rotor line current load and additional components of the rotor current with the main induction wave in the clearance causes tangential forces. However, integrated over the surface of the rotor they do not contribute greatly to the pulsating moment of an asynchronous electric motor of frequency ω_r .¹

All rotor current components take part in creating the magnetic field of the rotor, in which there are field components determined by the variable conductivity of the air gap with dynamic eccentricity. New components have frequencies $\omega_1 \pm \omega_r \pm \omega_r$, though their amplitude is essentially lower. They induce current in the stator winding, which interacts with the main line current load of the rotor creating tangential electrodynamic forces at frequencies ω_1 and $2\omega_r$. The pulsating moments acting on frequency $2\omega_r$ in an asynchronous electric motor with dynamic eccentricity of the clearance are not usually enough to significantly change the low-frequency vibration of the motor; nevertheless, they exert considerable influence on the selection of diagnostic parameters.

In two-pole asynchronous electric motors the modulation frequency of the magnetic field waves during dynamic eccentricity coincides with the frequency of the pulsating moment appearing as a result of electric asymmetry of the rotor; nevertheless, in multipole asynchronous electric motors ($p > 1$) these frequencies vary, which makes it possible to distinguish between two types of defects causing angular modulation of rotor rotational frequency by different frequencies $2s\omega_1$ and $2ks\omega_1/p$.

The static eccentricity of the clearance in an asynchronous electric motor results in current changes or one of the sections of the stator winding nearest to the point with minimal clearance: it is equivalent to presenting an "additional" single-phase winding in stator. An analogous effect has caused short-circuited

turns in the winding or in the active stator armature, as well as incorrect connection of winding sections.

Since the symmetry axis (in radial direction) of the static eccentricity of the clearance may not coincide with the axis of one of the stator windings, the "additional" stator winding partially performs the function of an additional pole in the asynchronous electric motor, which may result in new vibration components characteristic of an asynchronous electric motor with the number of pole pairs equal to $p \pm 1$. The parameters of these vibration components may also be used as indicators of static eccentricity of the clearance; though these parameters have no unambiguous connection to the defect value.

With static eccentricity of the clearance, saturation of the toothed zone of the stator and/or rotor is also possible. This zone is fixed with respect to the stator and has a reverse circular speed of rotation ω_r relative to the rotor. Nonlinear limitations of the main wave of the magnetic field result in the "additional" stator harmonics, in addition to the field with frequency ω_1 , creating component fields with the frequencies $(2k + 1)\omega_1$, $k = 1, 2, 3, \dots$, rotating in different directions. As in the case of static eccentricity without saturation of the toothed zone, a feedback current appears in the rotor and with frequencies $(2k + 1)\omega_1$; this current interacts with the stator main field, creating pulsating moments with frequencies $2(k + 1)\omega_1$. The diagnostic aspects of greatest interest are vibration components of electromagnetic origin with frequencies $4\omega_1$ and $8\omega_1$, which are practically absent in defect-free asynchronous electric motors.

The diagnostic features of defects may be divided into two main groups. Referred to the first group are features associated with the change of low-frequency vibration of the asynchronous electric motor starting with the frequency of $\omega_r/2$ and finishing with frequencies of $12\omega_1$. The distinguishing peculiarity of this group of features is their independence of the number of teeth in rotor and stator. The second group of features is coupled with the changes in the teeth components of vibration of an asynchronous electric motor; it is more sensitive to the emergence and growth of defects; nevertheless, it requires the presence of information about the number of teeth in the rotor (Z_r) and the stator (Z_{st}).

Some types of defects, the diagnostic features of which are coupled with the appearance of amplitude or frequency modulation of vibration components of electromagnetic origin in an asynchronous electric motor, may be detected and identified by a one-time measurement of vibration. It should be taken into account that many vibration components with frequencies that are in multiple to the rotor rotational frequency may be of mechanical and electromagnetic origin, and their modulation may refer only to one of the components.

All diagnostic features of main defects of an asynchronous electric motor and violations of the normal supply conditions are presented in Table 1. The table presents the values of frequencies of low-frequency vibration components, the amplitude of which changes

Table 1 Frequencies of Vibration Components Corresponding Defects of Asynchronous Electric Motors and Their Supply Voltage^a

Ref. No.	Designation of Defect	Growth of Low-Frequency Vibration	Growth of High-Frequency Vibration	Notes
1	Defects of stator windings	$2f_1$ (R, T)	$kf_{Z_{rt}} \pm 2f_1$

^a Where f_1 = frequency of supply voltage, Hz
 f_{rt} = frequency of rotor rotation, Hz
 $f_{Z_{rt}} = f_{rt}Z_{rt}$ or $f_{Z_{rt}} = f_{rt}Z_{rt} \pm 2f_1$ = toothed frequencies of the rotor, Hz
 $f_{Z_{st}} = f_{rt}Z_{st}$ = toothed frequency of the stator, Hz
 Z_{rt} = number of rotor teeth
 Z_{st} = number of stator teeth
 S = rotor slippage
 k, k_1 = integers
 R, T = radial and tangential directions of vibration excitation

(grows) with appearance (growth) of defects. Also shown in the table are the frequencies of vibration of toothed components, the structure of which changes both with the appearance of the above-mentioned defects and with deviation of the rotor/stator surface shape from the correct shape (ovality, "facedness," etc.). For the purpose of uniformity of presentation of tables with diagnostic defect features for various types of machines and equipments, the frequencies are given in linear units of f (hertz).

In making diagnostic measurements of low-frequency vibrations of asynchronous electric motors, particular attention should be paid to the selection of the place and direction of vibration measurement, since one portion of vibration components is excited by radial forces and the other portion by pulsating moments. The optimum may be for the measurements to be performed in two planes, in which the rotational supports of the asynchronous electric motor are located and in two directions (radial and tangential). The measurement points are selected, as a rule, on the body of the asynchronous electric motor at a distance from the point of its fastening to the foundation. For practical diagnostics it is sometimes sufficient to perform one vibration measurement in one direction for asynchronous electric motors of small size and two measurements for motors of

great size. To align the diagnostic and monitoring measurements, it is preferred to perform them on the body (end brackets) of the asynchronous electric motor in the horizontal direction with displacement with respect to the rotor rotational axis.

To effectively detect defects it is necessary to measure vibration spectra of the asynchronous electric motor with high-frequency resolution. Thus, in the frequency range up to triple the rotor rotational frequency, the spectrum bandwidth should be not more than $f_1/400p$, where f_1 is the supply voltage frequency in hertz. In the frequency band from $2f_1$ to $13f_1$, the spectrum bandwidth should not exceed $f_1/100$ Hz, and in the vibration toothed zone, not more than $f_1/5p$.

4 VIBRATION DIAGNOSTICS OF SYNCHRONOUS MACHINES

Synchronous machines may be used as generators of ac voltage or as motors, particularly in high-power drives. The possibilities of diagnostics of the technical condition of synchronous machines by the vibration signal are somewhat narrower than the vibration diagnostics of asynchronous electric motors, but they are wider than the possibilities of diagnostics by the current or electromagnetic field.

The synchronous machine stator field, just like in an asynchronous electric motor, is created by the power winding distributed along the slots of the stator active armature. The peculiarity of the stator and the rotor of large-size synchronous machines is the use of direct gas or water cooling systems. The design solutions used for this purpose exert an essential influence on the operation and vibration of these machines.

The rotor of a synchronous machine may be defined, in particular in slow-speed machines or hydrogenerators, or have a distributed excitation winding (in slots). In the first case, the sinusoidal shape of the excitation field is provided by the shape of the poles (irregular air gap between the pole and the stator), and in the second case it is ensured by the distribution of the excitation winding in the slots of the rotor. Active armatures of the rotor and stator are made of laminated steel, but in the rotor armature the steel sheets have no insulation coating, just like in the stator core. In the rotors of explicit-pole machines with power over 100 kW, a short-circuited winding is installed, which is the analog of a squirrel's cage in the asynchronous electric motor.

The rods of a squirrel's cage are placed in the slots on the poles of a synchronous machine and are interconnected over the end surfaces with current conducting plates. If a synchronous machine works in the motor mode, the squirrel's cage is used as a starting winding. If a synchronous machine works in the generator mode, the squirrel's cage performs the function of a damper that reduces the high-frequency components of the field and output voltage. In implicit-pole machines, this winding may be absent, and its function may be performed by the active rotor armature, which is most often made of a single forging of special steel.

The starting (damping) winding of the synchronous machine influences essentially the process of formation of oscillatory forces of electromagnetic origin. All harmonics of the magnetic field in the clearance having a circular rotational frequency Ω_i , differing from the rotor rotational frequency $\omega_{\pi} = \omega_1/p$, excite current in the damper winding and/or rotor armature. This current compensates the corresponding harmonics of the magnetic field in the clearance and reduces the radial oscillatory forces excited by these harmonics. At the same time the current in the damper winding (armature), by interacting with the main wave of the stator magnetic field, excites essential tangential oscillatory forces that may result in great (by amplitude) pulsating moments acting on the stator and rotor of the synchronous machine.

Defects of electromagnetic origin exerting an influence on the vibration of motors and generators include defects of rotor windings (excitation and damper), static eccentricity of the air gap, stator winding defects, and excitation current source defects. In addition to the above-mentioned defects, vibration of synchronous machines is influenced by the asymmetry and nonlinear distortions of the supply voltage. The radial oscillatory forces of electromagnetic origin and the vibration excited by them in defect-free synchronous machines are determined in the same way as in asynchronous electric motors.

When determining the frequencies of high-frequency components of vibration and evaluating their amplitudes in explicit-pole and implicit-pole machines, it is necessary to take into account a number of peculiarities of these machines. In explicit-pole synchronous machines, in addition to the toothed vibration components, there are also high-frequency components presented that are determined by the higher harmonics of the stator magnetomotive force appearing due to the discreteness of its windings and the higher harmonics of the clearance conductivity due to its irregularity determined by the shape of the poles.

The amplitudes of higher harmonics of the stator magnetomotive force are a $k_{st}pq$ times lower than the amplitudes of the main magnetomotive force harmonic, where p is number of poles, q is the number of stator slots per pole and phase, and k_{st} is the number of the harmonic. The number of these magnetomotive force harmonics is equal to ω_1 while the spatial order is $r = (6q' + 1)p$, where $q' = \pm 1; \pm 2; \pm 3; \dots$ ¹

The amplitudes of higher harmonics of the clearance conductivity determined by the shape of the poles is $3j_{\pi}$ times less than the mean value of the clearance conductivity; their frequencies are equal to $2j_{\pi}\omega_1$ and the spatial orders are $r = 2j_{\pi}p$. Thus, the magnetic field in the clearance of an explicit-pole synchronous machine has a harmonic row of flux density components with frequencies $(2j_{\pi} \pm 1)\omega_1$ and spatial orders $2pj_{\pi} \pm (6q' + 1)p$. The interaction of these components with the main wave of flux density brings about radial oscillatory forces between the stator and the rotor.

The components differing from the toothed vibration frequency of $\pm 2\omega_1$ may contribute greatly into the vibration of electromagnetic origin of explicit-pole synchronous machines¹ due to the low spatial order of the oscillatory forces.

The peculiarities of the toothed components of vibration of defect-free synchronous machines excited by radial sources due to the "toothedness" of the poles are determined by the distance between the teeth and the inner surface of the stator, as well as the angular distances between the teeth of one, and adjacent poles are not being strictly equal. Therefore, the vibration components determined by the 'toothedness' of the rotor of a synchronous machine have amplitude and angular modulation, that is, they have a great number of side components with frequencies $k\omega_{\pi}Z_{\pi} \pm k_1\omega_{\pi}$, where $k_1 = 1, 2, 3, \dots, k_2 = 1, 2, 3, \dots$ ² When determining the frequency of toothed vibration governed by the toothedness of the poles, there is a great probability of an error since the rated number of teeth may differ from $2pZ_{\pi}$, where Z_{π} is the number of teeth at the pole of the synchronous machine.

As a rule, the full number of slots (teeth) at the poles of a synchronous machine is close to the number of stator slots; therefore, certain vibration components due to the toothedness of the rotor and stator may coincide. It should be noted that the harmonics of clearance conductivity due to the toothedness of the rotor are smaller than the analogous harmonics due to the irregularities of the clearance between the poles and

the stator; therefore, the vibration components of the synchronous machine determined by the toothedness of the rotor are essentially less. As a consequence, when calculating the vibration of the synchronous machine, these components are usually not taken into account. At the same time, they may carry an essential diagnostic information value.

In implicit-pole defect-free synchronous machines the number of high-frequency components of vibration of electromagnetic origin is less than in explicit-pole synchronous machines and asynchronous electric motors. Most often the strongest high-frequency components of vibration in implicit-pole synchronous machines are determined by the interaction of the higher harmonics of the stator magnetomotive force with the toothed harmonics of the rotor conductivity. The reason is that the higher harmonics of the stator magnetomotive force have a spatial order $r = (6q' + 1)p$ where $q' = \pm 1, \pm 2, \pm 3, \dots$, while the number of rotor slots is usually presented by the value $Z_{\text{r}} = 6q''p$ where $q'' = 2, 3, 4, \dots$; here the excitation winding occupies two thirds of possible rotor slots, which makes it possible to reduce to zero the higher spatial harmonics of the exciting field with the order multiple to three. The other harmonics of the exciting field, except the fifth, make up less than 1% of the main harmonic. Very often in the rotors of implicit-pole synchronous machines the slots free of windings are not machined, that is, the rotor has $2p$ "great" teeth, while the radial oscillatory forces of the order of toothedness of the rotor acquire amplitude modulation due to these teeth. For such rotors, during calculation of the frequency of toothed vibration it is necessary to take into account the specified value $Z_{\text{r}} = 3Z'_{\text{r}}/2$ where Z'_{r} is the real number of rotor slots as specified in the technical documentation.

The next task of describing the vibration of defect-free synchronous machines is the determination of the pulsating moments and tangential vibration of the machine when it is fed from the supply mains with asymmetric voltage and distorted voltage shape.

With asymmetry of supply voltage in explicit-pole machines and implicit-pole synchronous machines, the current in the stator and the magnetic field in the clearance, same as in asynchronous electric motors, represents a sum of direct and reverse sequences having frequency ω_1 .

The current component of the reverse sequence in the stator interacts with the main wave of the excitation field creating tangential electrodynamic forces. The stator reverse sequence magnetic field component interacts analogously with the rotor excitation current. Since the spatial orders of the waves of the field and current are the same, the tangential forces (integrating over the surface of the rotor and stator of the synchronous machine) create a pulsating moment of forces with frequency $2\omega_1$. This moment excites tangential vibration of rotor and stator armature in the synchronous machine. In large synchronous machines the stator armature is usually resiliently (in tangential direction) suspended to the machine housing; therefore, in such machines the vibration of the housing on

frequency $2\omega_1$ may vary within a small range in case of asymmetry of supply voltage.

With nonlinear distortions of the supply voltage, just as in case of asynchronous electric motors, currents are induced in the rotor armature and in the damper windings of the synchronous machines. These currents are determined by the frequency and direction of rotation of the higher harmonics of the stator magnetomotive force. Correspondingly, the induced currents, by interacting with the variable component of the magnetic field, excite tangential electrodynamic forces and pulsating moments with frequencies $6q'\omega_1$.

In implicit-pole synchronous machines the pulsating moments appearing due to nonlinear distortions of the voltage may be calculated in the same way as for asynchronous electric motors. It should be noted that the values of currents $I_{6q'-1}$ and $I_{6q'+1}$ with equal distortions in the synchronous machine may be less, and for evaluation of the pulsating moments, they should be better determined experimentally.

In explicit-pole synchronous machines with equal initial phases of the supply voltage higher harmonics, there are pulsating moments with frequencies $6q'\omega_1$.² In large synchronous machines with resilient suspension of the stator armature in the housing of the machine, the vibration of the housing at frequencies $6q'\omega_1$ with maximum admissible nonlinear distortions of the supply voltage may be considerably lower than the vibration excited by the electromagnetic forces at other frequencies.

The vibration of the synchronous machine depends essentially on the quality of the excitation voltage in accordance with an addition to the constant component may be present in harmonic components of various frequencies. The variety of means of forming the excitation voltages does not allow thorough determination of the spectrum composition of the excitation current; therefore, in practice it should be determined experimentally by measuring its spectrum. For this purpose, it is best to use a hook-on meter and those facilities for analysis of electric signals used for analysis of vibration signals.

Very often rectifiers are used for feeding the excitation windings of synchronous machines. In the absence of defects in the rectifier, the output of the rectifier in addition to the constant component may have additional harmonic components with frequencies $6k\omega_1$ where $k = 1, 2, 3, \dots$, where ω_1 is the frequency of the supply voltage. Depending on the electric circuit of the rectifier, tolerances for its characteristics and possible defects, the output voltage may contain harmonic components with frequencies $2k\omega_1, 3k\omega_1$ and other frequencies.⁶ Variable voltage components may also appear at the output of the rectifier in the presence of asymmetry or nonlinear distortions of the supply voltage in the electric mains used to supply voltage to the rectifier.

The variable components of the synchronous machine excitation current give rise to components of the excitation magnetic field of the same frequency. In turn, these excitation field components induce currents with the same frequencies in the damper winding and

the active steel of the rotor. The variable components of the excitation field interact with the main wave of the stator current; the variable components of the current in the damper windings (steel) of the rotor interact with the main wave of the magnetic field and thus create tangential electrodynamic forces of zero spatial order and, as a result, pulsating moments acting on the rotor and stator in opposite directions. The frequencies of the pulsating moments coincide with the frequencies of the corresponding variable components of the excitation current.

The amplitude of the pulsating moment effective in the synchronous machine having a frequency equal to the corresponding excitation current component is proportional in first approximation, to the load moment of the synchronous machine. The ratio of the variable component is proportional to the constant component of the excitation current. As a rule, the variable components of the excitation current do not exceed a value of 1 to 2% of the constant component and do not exert a great influence on the electromagnetic vibration of the synchronous machine. At the same time, in diagnostic tasks it is necessary to take into account even the synchronous machine vibration components associated with nonlinear distortions of the excitation voltage.

When determining the technical condition of the synchronous machine, it is necessary to evaluate the state of the brush-commutator assembly. Its defects, as a rule, cause pulsations of resistance of the electric excitation circuit and, as a result, pulsations of the excitation current. But, as distinct from the pulsations caused by the defects of the rectifier, these pulsations represent a sum of harmonic components with frequencies $k\omega_{\pi}$. This permits separation of the indications of defects of the brush-commutator assembly from those of the rectifier as a result of analyzing the synchronous machine excitation current spectrum. It is more difficult to detect defects of the brush-commutator assembly using the vibration spectra of the synchronous machine, since it is difficult to separate their indications from the indication of mechanical defects of the rotor or connecting couplings.

For the synchronous machine electromagnetic system most defects are associated with the excitation windings and static eccentricity of the clearance. The defects associated with the excitation windings are manifested in the change of the excitation field shape. These changes are greatest in the multipole synchronous machines in which, in the presence of winding defects (or change of the shape of poles in explicit-pole synchronous machines), the excitation field becomes asymmetric in the radial plane with respect to the axis. As a result, an additional radial electromagnetic force rotating with the frequency ω_{π} appears, as well as the pulsating moment with the frequency $2\omega_{\pi}$.

The next (in amplitude) radial oscillatory forces, as in the case of asynchronous electric motors with dynamic eccentricity of the clearance, have frequencies $2\omega_1 \pm k\omega_{\pi}$. They are a consequence of the amplitude modulation of the radial forces excited by the main wave of the magnetic field, in the vibration test point on the body of the machine.

In addition to the above-mentioned peculiarities of influence of the asymmetric excitation field on the vibration of the synchronous machine, it is possible to additionally note the growth of the pulsating moments acting in the machine having frequencies $k\omega_1$ and an amplitude modulation of toothed components determined by the toothedness of the stator, characterized by frequencies $k\omega_{\pi}$.

At an early stage of defect development, various indication features may be used for detecting defects in the form of a static eccentricity of the clearance and defects of stator windings for various types of synchronous machines. Thus, in large synchronous machines with resiliently suspended stator armatures, it is better to detect these defects by the tangential growth of stator vibration at a frequency of $2\omega_1$. The same defects in implicit-pole synchronous machines may be detected by the growth of toothed components of vibration and side components with frequencies $k_1\omega_{Z_{st}} \pm k_2\omega_1$.

Most difficult is the detection of clearance eccentricity in explicit-pole synchronous machines in which even in the absence of defects there are noticeable vibration components with frequencies $k_1\omega_{Z_{st}} \pm k_2\omega_1$. The toothed components determined by the toothedness of the rotor are also difficult to identify and separate from the toothed components determined by the toothedness of the stator. Therefore, it is possible to indirectly identify defects by the growth of the side component of vibration with frequencies $k_1\omega_{Z_{st}} \pm k_2\omega_1$ with $k_2 > 2$, and if it is possible to separate groups of toothed components determined by the toothedness of the rotor with frequencies $k_1\omega_{Z_{st}} \pm 2k_2\omega_1 \pm k_3\omega_{\pi}$, in which k_1 and $k_3 = 1, 2, 3, \dots$, and $k_2 = 0$ or 1 , then by the growth of the side components with $k_2 = 1$.

The diagnostic features of the main defects in explicit-pole synchronous machines are summarized in Table 2, and those of implicit-pole synchronous machines in Table 3. The tables present frequencies (in linear units) of those vibration components in the synchronous machine for which the amplitude grows with the appearance and growth of the specified defects.

In making diagnostic measurements of low-frequency vibration of synchronous machines particular attention should be paid to the selection of the location and direction of measurement of vibration since with appearance of many defects the tangential vibration grows predominantly, this vibration being excited by the pulsating moments. The optimum test points for measurements in large synchronous machines with resilient suspension of the stator are points on the stator core with the direction of measurement tangential to the core. In other synchronous machines it is recommended to perform the measurements on the housing of the machine, just like in asynchronous electric motors.

5 VIBRODIAGNOSTICS OF DIRECT CURRENT (dc) MACHINES

Direct current machines may be used both as generators and as motors particularly with variable-speed

^a See footnote to Table 1 for definitions.

drives. A large starting moment of dc machines is the main reason of using them in transport vehicles as traction motors.

The main design peculiarity determining the vibration of electromagnetic origin in dc machines is a large value of the air gap between the armature and the pole piece, which sometimes reaches a value of 10 to 15 mm in high-power dc machines. The lifetime and overhaul period of operation of dc machines is less than that of asynchronous electric motors or synchronous machines first of all due to large currents in the armature and accelerated wear of the brush-commutator assembly. Hence, the task of monitoring the technical condition and performing diagnostics of dc machines is the greatest out of all types of electric machines.

In recent years regulated static rectifiers are more widely used for feeding and adjusting the rotational frequency of dc machines, which makes it more difficult to solve the task of monitoring the technical condition of the machine both by the parameters of armature and excitation current, and by vibration, due to pulsations of the supply voltage.

The possibilities of vibration diagnostics on dc machines are not good due to lack of spectral composition of electromagnetic vibration. Therefore, it is recommended to complement the vibration diagnostics of the dc machines with diagnostics using armature current spectrum, and for the case of independent excitation, by using excitation current. The effectiveness of vibration diagnostics of dc machines increases in cases where there is a possibility

of comparing vibration of the machine with two different loads (resistance) in operating modes.

The low-frequency vibration of electromagnetic origin in the dc machines is determined, as in ac machines, by three main causes, namely, the peculiarities of the design, the defects, and the presence of pulsations of the dc supply voltage mains.¹ Since the electromagnetic field of dc machines does not rotate, there are no intensive vibration components with frequency $2p\omega_n$ determined by rotation of the excitation field. As a result, the main contribution to vibration of electromagnetic origin in defect-free dc machines is made by the toothed components determined by the toothedness of the armature.

Out of the forces of electromagnetic origin acting on the housing of the defect-free dc machine are predominantly radial oscillatory forces of the toothed frequency and its upper harmonics, which may be presented by the components applied to the edges of the pole pieces. The reaction forces act on the armature; and the sum of all components of the reaction forces applied to the armature in a defect-free dc machine is equal to zero.

The value of each of these components at the frequency ω_z equals as follows¹:

$$F_{r,\omega_z} = B_0^2(k_c - 1)\ell b/2\pi\mu_0\alpha \quad (2)$$

where B_0 = mean flux density value in the clearance

k_c = Carter (air gap) coefficient

ℓ, b = length and width, respectively, of the pole arc

α = number of slots over the length of a pole arc

μ_0 = magnetic permeability of air

With half-integer value $\alpha = q' + \frac{1}{2}$, where q' is the number of the forces acting on the opposite ends of the pole, pieces are in-phase and are summed up, and with an integer value $\alpha = q'$ a bending moment acts on the pole. The order of oscillations of the frame under the action of these forces and moments is determined by the phase states between the forces acting on the adjacent poles.

Generally, the accuracy of the manufacture and the assembly of a dc machine is such that, depending on the value of the loading moment, the symmetry axes of the magnetic field under the poles are displaced, while the widths of the polar arc over the magnetic field change within a short range, but sufficiently to change the spatial order of the oscillatory forces and vibration. To reduce the value of these forces and to smooth down the boundaries of transition from some forms of oscillations to others, beveling of the slots of the armature for one slot division and/or beveling of the pole edges is performed. The vibration of a defect-free dc machine with beveled slots at the toothed frequencies may be evaluated by assuming the action of two opposing radial forces with a value $F_{r,\omega_z}/kp$ where $k = 1, 2, 3, \dots$, on the frame in the opposite points that excite ring oscillations of the second order $p = 2$.

When the dc machine works under load, the magnetic field in the clearance changes its shape, increasing in the direction of one edge of the pole piece.⁶ Correspondingly, the oscillatory force acts predominantly on one edge of the pole piece and grows in value by up to two times with full load of the dc machine. While doing so, the spatial shape of the oscillatory forces has a zero order, and the vibration excited by these forces in a defect-free dc machine changes only within a limited range. Nevertheless, even with small static eccentricity of the clearance, the toothed vibration of the machine may grow substantially since oscillatory forces of the first spatial order appear; for these forces the mechanical compliance of the frame with the poles is many times more than for the forces of the zero and higher orders.

In addition to the radial forces of the toothed frequency the poles and the armature of the dc machine are acted upon by tangential forces. Thus, the edge of each pole (and armature) is acted upon by the tangential force determined by the following expression:

$$F_{t,\omega_z} = 2B_0^2(k_c - 1)\ell\delta/\pi\mu_0 \quad (3)$$

where δ is the value of the clearance.

At idle revolutions, the tangential forces acting on the two edges of one pole are antiphase, and the total pulsating moment in the dc machine at the toothed frequency is close to zero. Nevertheless, under load the force acting on one edge of the pole grows while the force acting on the other edge reduces, and this may bring about the growth of a pulsating moment and vibration in the dc machine.

The vibration of defect-free dc machines changes greatly when fed from a static rectifier with pulsations of the output voltage. The spectral composition of these pulsations depends essentially on the characteristics of the static rectifier. Many up-to-date static rectifiers contain low-frequency filters used to smooth the rectified voltage of the ac mains, and regulation of the output voltage in them is performed by pulse width regulators with high (usually several kilohertz) switching frequency and subsequent filtration of the output voltage. But since many machines continue to use simple thyristor regulators with considerable pulsations of the output voltage, it is necessary first of all to control the spectrum composition of the armature current (excitation) and secondly to evaluate its influence on the vibration of a dc machine.

In most regulated rectifiers, the frequency of pulsations of the output voltage is a multiple of frequency of the ac voltage ω_1 in the supply mains, and the main harmonics of the armature current belong to the harmonic series $k\omega_1$ where $k = 1, 2, 3, \dots$; here the harmonics maximal in amplitude may have frequencies $2k\omega_1, 3k\omega_1, 6k\omega_1$, and others. In this connection, the vibration diagnostics of a dc machine should be performed at such rotational frequencies with which the harmonic series of the vibration components with frequencies $k_1\omega_n$ and $k_2\omega_1$ are well separated in the frequency band. The optimal rotational

frequencies may be considered such that frequencies $k\omega_{\pi}$ and ω_1 where k is the whole number of ω_1/ω_{π} , differ by 5 to 10%.

The vibration of the dc machine is affected by defects of the brush-commutator assemblies, armature windings (additional poles), the static eccentricity of the clearance (skewing of the poles), loose pole fastenings, and defects of excitation windings. Defects of the brush-commutator assembly occur most often. They are manifested in the form of nonuniform wear of the brushes and the commutator and the protrusion of separate insulation gaskets between the bars or rupture of bars (commutator lugs). Nonuniform wear of the brushes and/or commutator rupture most often cause problems in the process of commutation of the current of the armature, predominantly with one of the brushes in one of the commutator zones limited by the number of bars. Absence of contact between the brush and one of the commutator bars or rupture of a bar or a section of the winding leads to redistribution of current in the armature winding; the current is connected through balancing connections on the brush pairs remaining intact. With partial load of a dc machine there may be no impairment of the process of commutation, but a pulsating moment with frequency $2p\omega_{\pi}$ starts acting in the machine. This moment tends to cause growth of tangential vibration of the machine at frequencies of $2kp\omega_{\pi}$.

In the case of skewing of auxiliary poles, as well as in the case of appearance of short-circuited turns in the windings of the auxiliary poles or in the excitation of windings, the current commutation conditions may be impaired in the brush zone of the defective pair of poles. The variable components of the armature current with commutator frequencies $k\omega_v = kZ_v\omega_{\pi}$ where Z_v is the number of commutator bars that start to grow, and hence there appears vibration of the dc machine at the commutator frequencies. In most dc machines, as the supply voltage increases, the number of commutator bars is several times greater than the number of teeth in the armature; this makes it possible to separate the higher harmonics of the armature current and dc machine vibration into toothed and commutator components.

The growth of commutator components of the dc machine vibration, particularly under load, is one of the main diagnostic features of defects in the brush-commutator assembly and the auxiliary poles, but identification of the defects by these features is difficult. For preliminary identification of a defect it is possible to use the properties of the side components of vibration on commutator frequencies. Thus, if there are no side frequencies, the most probable reason of commutation violation is a defect in the poles or their windings. If the side components of vibration are present and differ from the commutator frequency by frequencies $k\omega_{\pi}$, then mechanical defects, for instance, rupture of the commutator or wear of the brushes (commutator) are most possible, and if side components are present differing by frequencies $2kp\omega_{\pi}$, then defects of the commutator bars or armature winding are most probable.

The possibilities of identification of dc machine defects and in a number of cases of increasing

the sensitivity of the diagnostic features to incipient defects may be expanded by conducting parallel measurements and analysis of the armature current spectra. In the most general case, the armature current may contain harmonic component series with frequencies kf_{π} , $2kp f_{\pi}$, kf_{Z_v} , and kf_{Z_e} and, depending on presence of various defects in the electromagnetic system of the dc machine, with side components differing by frequencies $\pm kf_{\pi}$, $\pm 2kp f_{\pi}$, and $\pm kf_{Z_v}$.

In real conditions, there may be many more harmonic components of various frequencies in the spectrum of the armature current due to variable loads in the dc electric drive and from the other machines coupled to the dc motor. This makes it possible to obtain additional diagnostic information on the operation and state of the coupled machines.

In certain cases it is possible to measure and compare current spectra in the slip rings of different pole pairs of the dc machine. This makes it possible to determine in which machine/pole pair there are defects detectable by vibration or armature current, and sometimes to specify the value of the defect.

The features of the main defects in dc machines during their diagnostics by vibration spectra and/or armature current are summarized in Table 4. The table presents frequencies of those vibration components and armature current components that grow as a result of emergence and growth of the said defects.

For monitoring vibration during dc machine diagnostics, it is better to select the test points on its housing in the plane of fastening of the end brackets. As in diagnostics of asynchronous electric motors, it is recommended to perform vibration diagnostics of large-size machines by measuring the vibration at two points near both end brackets. In low-power machines (less than 50 to 100 kW) it is possible to measure vibration in one point, predominantly from the side of the commutator where high-frequency commutator vibration may appear, this vibration being not only electromagnetic in nature but also of mechanical origin.

The direction of measurement of vibration should not be radial to the axis of rotation of the armature since in this case the results of measurements may change little with the appearance of pulsating moments at low and medium frequencies in the machine. It is best of all to prepare the place for fastening the measuring transducer so that it has equal sensitivity to the radial and tangential vibration and much lower (two to three times) sensitivity to the axial vibration of the machine housing.

When selecting the diagnostic model, preference should be given to group models, which use measurements of vibration spectra of the housing and armature current of dc machines in two operating modes, if possible, with a strongly varying load. For diagnostics of machines operating continuously in one mode of operation it is possible to use "historical" diagnostic models by accumulating the data of periodic changes (statistics) within the first year of operation with intervals not exceeding one month and introducing corrections into the model after each maintenance service of the machine.

Table 4 Frequencies of Vibration Components and Armature Current Corresponding to Defects in dc Machines and Pulsations of Supply Voltage^a

Ref. No.	Designation of Defect	Growth of Vibration Harmonics	Growth of Current Harmonics	Notes
1	Static eccentricity of clearance, skewing of poles	$f_{Z_{arm}}; f_{Z_v}$ (R, T)	$f_{Z_{arm}}; f_{Z_v}$	Growth of vibration when changing load modes
2	Defects of armature windings, rupture of commutator bars	$2pf_{Z_{arm}}$ (T) $kf_{Z_v} \pm 2pf_{rt}$ (R, T) $kf_{Z_{arm}} \pm 2pf_{rt}$ (R, T) $kf_{Z_v} \pm 2pf_{rt}$ (R, T)	$2pf_{rt}$ $kf_{Z_{arm}} \pm 2pf_{rt}$	
3	Defects of excitation windings	kf_{Z_v} (R, T)	kf_{Z_v}	Growth when changing load modes
4	Defects of commutation	kf_{Z_v} (R, T)	kf_{Z_v}

CHAPTER 73

PUMPS AND PUMPING SYSTEM NOISE AND VIBRATION PREDICTION AND CONTROL

1 INTRODUCTION

Hydraulic pumps are used for transporting chilled, hot, and condenser water or any other liquid in hydraulic systems. They are also used for transporting suspensions of liquid and solid particles from one location to another through pipes or closed/opened channels and passages. Common applications include use in processing plants, hydraulic fluid power, clean water supply, ships, and the like. Operation of a pump creates pressure pulsations, vibration, and noise, which can be spread by pipes (structure-borne noise) and by liquid (fluid-borne noise) far away from the pump itself, emitting noise (from pipes) around the whole pumping system. Noise generated by the pump depends on its type and size, on its power, and on the operating conditions (speed and load). Noise of the pumping system depends on its geometry and type and number of the built-in fittings and armatures. Noise and vibration of a hydraulic system can be controlled by proper selection or redesigning of the pump and/or pumping system and by optimizing of the operating conditions [for operating near the best efficiency point (BEP) and without cavitation]. Tuning of the operating frequency with regard to the resonance frequencies of the pumping system, and by proper balancing of all rotating masses, and the like is important.

2 TYPES OF PUMPS

Pumps are classified according to the principle of adding energy to the fluid into three main groups: kinetic, positive-displacement, and special-effect pumps (Fig. 1):

Kinetic pumps, in which energy is continuously added to the pumped liquid within the pump first by increasing the fluid velocity and then toward the end of the pump by increasing the delivery pressure, are subdivided into centrifugal or radial-flow, diagonal or mixed-flow, and axial-flow or propeller pumps (Fig. 1a). Centrifugal pumps are further divided into single and multistage pumps, with a volute collector or a multiple vane diffuser, with a straight vane or a Francis vane impeller, and with a fully open, a semiopen, and a fully closed impeller. Kinetic pumps are non-self-priming pumps but are the most widely used due to their high efficiency and reliable operation.

Special-effect kinetic pumps are in the form of peripheral (called also regenerative, turbulence, turbine, and vortex) pumps, partial-emission (called also

straight-radial-vane high-speed single-stage, vertical, paddle wheel according to Barske¹) pumps, and Tesla (called also disk and viscous shear) pumps (Fig. 1a). The peripheral pumps have many radial vanes mounted on the periphery of the disk that rotate within an annular chamber. Liquid within the casing is separated by rotating vanes into many particular elements (vortices) with a high level of recirculation. The partial emission pumps consist of an open or semiopen radial (90°) vane centrifugal impeller, which rotates with very high speed (15,000 to 30,000 rpm, and up to 120,000 rpm) in circular casing with a single emission point to a conical diffusion section. Partial emission pumps are used to relatively higher heads and lower capacities. The Tesla pumps have two or more rotating parallel disks in which a viscous drag is created. They must rotate very fast, usually above 10,000 rpm, in order for the viscous drag to generate the forces to move the liquid.

Positive-displacement pumps, in which energy is periodically added by application of force to one or more movable working elements (piston, gear, vane, screw etc.) in a cylinder or appropriate casing, are divided, according to the nature of movement of the pressure-producing members, into reciprocating and rotary pumps.

Reciprocating pumps are further divided into piston, plunger, and diaphragm pumps (Fig. 1b) with one or more cylinders. They are self-priming pumps and are used for high pressure and low capacity. The piston(s) or plunger(s) or diaphragm are driven through slider-crank mechanisms and a crankshaft from an external source; therefore, they have a pulsating discharge. The flow rate is varied by changing either the rotating speed or the stroke length. Reciprocating pumps need one-way suction as well as discharge check valves separating the discharge from the suction side of the pump. These valves may be in the form of a plate, wing or flapper, ball, plug, and slurry.²

Rotary pumps are divided into pumps with a single-rotor and multiple rotors. The single-rotor rotary pumps are further divided into vane (blade, bucket, roller or slipper, or flexible impeller vane), flexible tube or peristaltic, screw (single screw and single screw with eccentric or progressive cavity) pumps. The pumps with multiple rotors are circumferential piston (axial and radial), gear (external and internal), lobe or Root's, and screw (two to five screw) (Fig. 1c). Rotary pumps are also self-priming, but they do not

Figure 1 Types of pumps: (a) kinetic pumps, (b) reciprocating pumps, and (c) rotary pumps.

need valves or a crankshaft, therefore, they are relatively small and due to relative high efficiency are appropriate for pumping of liquids with high viscosities at medium pressures and capacities. Depending on the type, rotary pumps produce relatively small flows and pressure pulsations, so that the generated noise is much lower than with reciprocating pumps. This is also due to appropriate radial and axial clearances between the rotating elements and the casing that prevent mechanical contact and also due to utilization of a fluid film between the teeth at the gear or screw pumps, and between vanes and casing at vane rotary pumps, which reduces the impact and sliding effects. In spite of this, generated noise can be considerable, especially at the higher discharge pressures.

Special-effect pumps, in which energy is added by application of special physical principles, such as exchanging of the impulse or momentum in jet pumps (ejector or injector with water or vapor jet), by lifting power in air lift pumps, by pressure pulsation in hydraulic rams, or by applying Biot–Savart’s law in electromagnetic pumps, are rarely used and therefore beyond the scope of this section.

3 HYDRAULIC AND MECHANICAL SOURCES OF NOISE

Noise generated by a hydraulic pumping system consists of the noise generated by the pump itself, by the driving motor, usually a fan-cooled electric motor, which is beyond the scope of this section, and that generated by the pumping system, and is mainly hydrodynamic and partially mechanical in origin. Both types of noise origins are transmitted throughout the system over the fluid and/or structure as structure-borne sound before exciting the surrounding air and reaching us as noise. A pump as the prime mover is only part of a pumping system; therefore, we have to distinguish between the noise generated by the pump and the pumping system.

Noise generated by a pump depends on the pump type, on its geometry (size and form), and on the operating conditions (speed and load). The main sources

of noise in kinetic pumps are interaction between the impeller blade and the volute tongue or diffuser vanes in centrifugal pumps, and between the impeller blade and guide vanes in axial-flow pumps, so called blade passage frequency (BPF), followed by pressure fluctuations caused by turbulence, flow friction, flow separation, and vortices in the radial and axial clearances, especially between the open or semiopen rotor and the adjacent stationary part of the casing.

Major sources of internal noise in *reciprocating pumps* are piston-induced pulsation, piston mechanical reactions, and impacts in inlet and discharge valves, which are exerted by the up and down motion of a piston or plunger. Intermittent liquid flow and fluctuating dynamic forces and machinery imbalance of the reciprocating and rotating internal parts (pistons, crankshaft, etc.) are then sources of intensive noise. Additional sources of noise in reciprocating pumps are turbulence, flow friction, vortex formation from separated flow around obstructions, piston slap in a form of impact excitation, which is a result of the clearance between the piston and cylinder wall and the high pressure that pushes on the top of the piston during compression strokes.

Major sources of noise in *rotary pumps* are impact between teeth in gear pumps, friction between screws at the screw pumps, and sliding of the vanes on the casing in vane rotary pumps. When the cavities between the gear teeth are not filled completely by the incoming liquid, the resulting vortices in voids generate a distinct noise, similar in nature to flow separation in centrifugal pumps during recirculation. Additional sources of noise are turbulence and flow friction in compression spaces.

The magnitude and frequency of the noise vary from pump to pump and are dependent on the magnitude of the pump head being generated and the amount by which pump flow at off-design operation deviates from ideal flow at the design or best efficiency point (BEP). The last is especially important with the kinetic pumps producing minimum noise at BEP. At off-design operation, the emitted noise generated by kinetic pumps steadily increases toward a zero flow rate and toward free delivery (Fig. 2). At higher flow

Figure 2 Performance and noise characteristics of (a) a centrifugal pump, (b) axial-flow pumps, and (c) positive-displacement pumps.

Figure 3 Cavitation in centrifugal pumps: (a) pressure within pump, (b) NPSH determination according to Ref. 3, and (c) NPSH determination according to Ref. 4.

rate ($Q > Q_{BEP}$) this is due to laminar and turbulent boundary layer vortex shedding caused by higher flow velocity and turbulence, and at lower flow rate ($Q < Q_{BEP}$) it is due to flow separation at the impeller blades and diffuser or guide vanes, and internal recirculation in the impeller eye and impeller discharge (Fig. 4).

Another factor that increases noise of a pump is pump instability, which may be caused by cavitation and, in kinetic pumps, by the appearance of stall and surge. Cavitation in kinetic pumps can occur within the entire operating regime, whereas stall and surge can only occur at partial flow rate. Cavitation can occur without stall and surge, and vice versa. Cavitation in kinetic pumps occurs more easily at higher flow rates ($Q > Q_{BEP}$) due to the increased flow velocity and pressure drop.

Cavitation in pumps occurs when the absolute static pressure at some point within a pump or pumping system falls below the saturated vapor pressure of the fluid at the prevailing temperature conditions; the fluid starts to flash and vaporization occurs. Vaporization of the flowing fluid is connected with the onset of bubbles. The bubbles are caught up by the flowing liquid and collapse within the pump (valve or piping system) when they reach a region of higher pressure, where they condense. This process is accompanied by a violent collapse or implosion of the bubbles and a tremendous increase in pressure, which has the character of water hammer blows. The process of cavitation and bombardment of the pump surface by the bursting bubbles causes three different, undesirable effects: (a) deterioration of the hydraulic performance of the pump (total delivery head, capacity and efficiency), (b) possible pitting and material erosion in the vicinity of the collapsing bubbles, and (c) vibration of the pump walls excited by the pressure and flow pulsations and resultant undesirable (crackling or hissing) noise.

Cavitation in kinetic pumps (centrifugal, mixed flow, and axial) appears first at the point of minimum static pressure. In centrifugal pumps cavitation appear first in the region of the highest flow velocity, which is

usually on the inlet edges of impeller blades (see point *a* in Fig. 3a), or when the local static pressure p' falls below the vapor pressure p_v corresponding to the local temperature of the pumping liquid, $p' < p_v$. The bubbles so originated collapse in close proximity to impeller walls acting like impulses (impact waves) to the metal itself and eroding it. By development of the cavitation, the bubbles are spread upstream toward the suction nozzle and suction pipe, and downstream toward impeller blades, shrouds, guide vanes, and volute casing.

Cavitation in rotary pumps appears first in the suction pipe before the entry of fluid in the pump, as well as in gaps between the teeth and casing in gear pumps or the rotating elements and casing of any rotary pumps. In reciprocating pumps cavitation appears in the cylinder, at the beginning of the suction stroke and in the suction pipe. However, the cavitation damage in positive-displacement pumps is not as severe or loud as in centrifugal pumps due to lower speed at which they operate and the higher vapor pressure of the fluid usually pumped.

Since the implosion of the bubbles appears randomly and chaotically, turbulent noise occurs over a wide frequency spectrum or at a specific frequency, so that the onset of cavitation can cause a change either in the total noise level or just in a particular frequency band. Figure 2a shows emitted noise level for a centrifugal pump without (L_p) and with cavitation ($L_{p,cavit}$). The curve representing the A-weighted noise level with cavitation is approximately 3 dB higher than that without cavitation. In some cases the A-weighted noise level is due to cavitation up to 10 dB higher. To avoid cavitation process in a pump the static pressure p' in Fig. 3a has to be greater than the vapor pressure p_v of liquid at that temperature.

Cavitation is associated with insufficient suction head of the pump. Therefore, the beginning of cavitation within kinetic pumps can be obtained by determination of the net positive suction head (NPSH). The NPSH required ($NPSH_r$) value is a head that is required above the liquid vapor pressure at the place of the lowest static pressure, for example, point *a* in

Fig. 3a, in order to prevent the inception of cavitation and safe and reliable operation of pump. The difference between the actual pressure of the liquid available and the vapor pressure of that liquid is called the net positive suction head available (NPSH_a). When the NPSH_a is equal to or greater than the NPSH_r, the pump will not cavitate, and when the NPSH_a is less than that required by the pump, cavitation occurs.

The NPSH required is determined by a test in which the total head is measured at a constant speed, flow rate, and test water temperature, under varying NPSH conditions. Lowering the NPSH value to the point where the available NPSH is insufficient causes a cavitation sufficient to degrade the performance of the pump and the total delivery head deteriorates (Fig. 3b). The exact value of NPSH required for a centrifugal pump is determined by a 3% drop in the total delivery head (Fig. 3b) and represents the required or critical value at which cavitation is fully developed.³ An alternative procedure is to establish a constant NPSH available and then vary the pump flow by means of a discharge control valve until a 3% drop in the pump total delivery head is observed (Fig. 3c).⁴ The methods need a special test standard according to ISO 3555 standard,⁵ and a set of measurement results to determine the NPSH required value at different flow rate. At the centrifugal pumps NPSH required value decreases by decreasing the flow rate, that is, by decreasing flow velocity (see Fig. 3c). At the mixed-flow pumps NPSH required value increases at off-design operation, so toward partial flow rate as well as toward free delivery. At the axial-flow pumps NPSH required value increases at off-design operation much more steeply as by the mixed-flow pumps.

Instead of the ISO 3555 standard the sound pressure level of a discrete frequency tone, or a group of discrete-frequency tones, in audible range (between 20 and 20,000 Hz) can also be used for determination of the NPSH required or critical value as well as to detect the incipient of the cavitation process and its development. Experiments have shown that the maximum discrete-frequency tone (or group of discrete-frequency tones) corresponds to the 3% drop in the total delivery head. The discrete-frequency tone(s) with maximal changes can be at BPF/2 (Fig. 5a)^{5,6} or at any other frequency.⁷ The differences in the level of the discrete-frequency tone before the incipient of cavitation and after it was fully developed can be great enough (between 10 and 20 dB at a distance of 0.5 or 1 m, and up to 40 dB and more with microphone position in a near field) that it could also be used for control cavitation in the pump, by means of initiating an alarm, shutdown, or control signal via an electrical control system.⁵⁻⁹

Stall and surge appear in kinetic pumps at partial flow rates. In suction and discharge areas of the impeller, internal recirculation first appears and then rotating stalls and surge causing additional hydraulic noise. The internal recirculation and rotating stall (A and B in Fig. 4) start at approximately 80% of the design flow. When the flow rate is reduced further, a sudden decrease in static pressure occurs within the

Figure 4 Flow distribution in impeller of centrifugal pump at design and off-design operation.

rotating stalls and the stalls spread over the entire suction and discharge cross sections. When stall cells A and B in the suction and discharge side of the impeller merge, a surge phenomenon occurs causing an unstable pump characteristic. When a surge appears, a pump is not able to sustain the static pressure difference between the discharge and the suction sides of the pump. Water surges back through the pump impeller and its discharge pressure is momentarily reduced. The flow rate and pressure fluctuations at the surge cause an intense vibration and additional turbulent noise.

Noise in the piping system is a result of both the mechanical vibration excited by pump and piping system components as well as by the liquid motion in the pump and piping system. Mechanical noise sources are vibrating components or surfaces, such as pistons, unbalanced rotating elements, and vibrating pump housing, which is transmitted to the inlet and outlet pipe to which it is connected (even through a flexible connection), producing vibrations of pipe walls and acoustic pressure fluctuations in adjacent media. Due to its cylindrical and usually curved form, piping generates a (single and/or two-dimensional) cylindrical noise. In addition to the frequencies associated with the pump and flow, pipes also vibrate at their own natural or resonant frequencies. Liquid or hydraulic noise sources are the result of friction, turbulent flow, and vortex formation in high-velocity flow and pulsating flow. With positive-displacement pumps, pressure fluctuation due to flowing liquid is noticeable when repeating momentum impulses are imparted to the fluid, and partially also with centrifugal pumps due to the action of the impeller blades against the volute tongue.

The amount of vibration and noise transmitted through the housing and pipework depends on the rotational speed of the pump, operating pressure and capacity, flowing fluid properties (velocity, density, viscosity, temperature), the material and geometry of the housing and pipework, suction and pressure reservoirs, elbows, Y- and T- branches, restrictions, block and control valves, wall thickness, supporting and hanging elements of the piping system, and so on.

Another factor that causes intense noise from a piping system is instability caused by cavitation, water hammer, and system resonances:

Cavitation within piping system, with the danger of pitting and material erosion, is a result of pressure drops, usually with partially closed control valves, when the critical flow rate is reached or due to high flow velocity (for cold water above 7 m/s).

Water hammer is a result of transient pressure impact when a suddenly closed control valve abruptly interrupts steady flow in a pumping system, for example. The sudden interruption of flow results in an extremely sharp pressure rise at the point of interruption; the entire distribution system is then shock excited into vibration. Water hammer is a more serious problem in this type of installation when long pipelines are involved and when a motor-driven pump stops delivering water almost instantaneously.

4 SOURCES OF VIBRATION IN HYDRAULIC SYSTEMS

There are different sources of vibration within hydraulic system, but the main source is the pump built-in. The vibration generated within the pump can be transmitted to the pumping system, and vice versa, especially if they are coupled rigidly or mounted on a rigid basement or wall, without elastic elements, directly.

Vibration generated by a pump has mechanical and hydraulic origins and depends on the pump type, on its manufacture (first of all balancing of rotating masses), assembling and wearing, and on operating conditions (operating point). Mechanical sources of vibration are mechanical imbalance of the rotating or reciprocating masses, due to poor balancing or careless assembly. The vibrations of a kinetic pump are strongly dependent on the shaft vibration. Shaft vibration and its failures are strongly influenced by the torsional resonances of the system, which are the angular natural frequencies of the system caused by dynamic forces of mechanical and hydraulic origin. Additional sources of mechanical vibration are rotational subsynchronous [at $n/2$, n is the rotational speed in revolutions per second (rps)], synchronous (at n), and super synchronous (at $2n$, $3n$, etc.) resonance (foreign particles in the rotor, damaged impellers, contortion, due to deposits, corrosion, galled parts, and abrasion), rubbing, excessive wearing, bushing, excessive bore clearance of sleeve bearings or loose fits on the shaft or housing in the case of ball bearings causing poor support of the rotor; impacts, nonconstant friction (e.g., stick-slip, chatter), mechanical interactions, magnetic effects and so on.

Hydraulic sources of vibration are pressure pulsations, turbulent liquid flow, suction recirculation, stall and surge, blade passing frequency, hydraulic imbalance due to uneven flow distribution before the impeller and in all blade passages, misalignment or other leakage clearances, unsteady fluid flow (e.g., turbulence, vortex shedding), increased axial and radial hydraulic forces in the volute casing of a centrifugal pump at off-design operation; pump manufacturer casting/or machining defects, wear, oil-whirl, cavitation, and so on.

5 SOURCES OF VIBRATION AND NOISE IN PUMP COUPLING AND SUPPORTING ELEMENTS

A major source of externally induced vibration and noise is misalignment between the pump and its driver, which depend on the coupling used. There are two primary groups of coupling: rigid and flexible. Rigid couplings are used for direct coupling and for precise alignment, whereas the flexible couplings are used for accommodating a set amount of misalignment (angular, axial, and radial or parallel) between the driving and driven shaft, and also radial and axial loads on the motor bearings. Rigid couplings are in sleeve-type or flange-type and are used when the pump impeller is mounted directly on the motor shaft (monobloc pumps). Flexible couplings may be mechanically flexible and "material flexible." The mechanically flexible couplings are in gear or grid form, which need lubrication. The material-flexible couplings have a flexible element in steel, rubber, elastomer, or plastic material and do not need lubrication. They are in the form of metal disk or disk pack or in the form of contoured diaphragm, or as an elastomer in compression or shear type with rubber jaws on driving and driven shafts corresponding to the number of cogs belt or a central spider on the flexible element with several radial segments.

There are also special types of couplings to transmit power with independent input and output shaft that allow desired adjustments of load speeds. Such couplings are the eddy-current slip couplings and fluid couplings (in hydrokinetic, hydrodynamic, hydroviscous, or hydrostatic form) using fluid (natural or synthetic oil).

A second source of externally induced vibration and noise at a pump are supporting bearings, with which it is equipped. The hydraulically and mechanically produced noise and other failings of the pump rotating and moving elements are transmitted over the bearings to the pump housing and as structural noise throughout the pumping system. Most pumps are equipped with external bearings in a classical three-bearing arrangement, journal or sleeve type (with hydrodynamic fluid film), antifriction (rollers, tapered rollers, or bearings in single or multiple rows), and magnetic bearings. At normal operation of a journal bearing the shaft forms a liquid film of the lubrication oil completely separates it from the bearing. The antifriction bearings operate with a very low coefficient of friction associated with rolling motion as distinct from sliding motion. To minimize the heat generated by sliding friction, antifriction bearings require oil or grease lubrication. The magnetic bearings are free from contact within the bearings, therefore they produce the lowest mechanical noise among all type of bearings, follow the journal or sleeve and antifriction bearings, which are the noisiest.

Vibration problems and noise in a pump increase when a failure in the bearings and/or coupling misalignment occurs. Bearing failure may be caused by water or product contamination in the bearing housing or by highly unbalanced radial loads, which can result

from operating at or near shutoff. Nonconstant friction forces usually are caused by poor lubrication, at low shaft speed or low fluid viscosity in journal bearings, when the strength of the liquid film is insufficient to support the load on the bearing and the shaft rubbing the bearing, or by unfavorable combinations of sliding interface materials, geometric arrangements, and sliding velocities. Damage of the rolling bearings causes vibrations at the integer number of rotational frequency, whereas the oil whirl in hydrodynamic bearings causes vibrations at a fraction of rotational speed. Poor lubrication and defects in the rolling elements or races in antifriction bearings exhibit very high frequency resonance and noise of about 20 kHz.

6 SOUND SPECTRA OF PUMPS AND PIPING SYSTEMS

Pumps and piping systems generate broadband or turbulent noise spectra with pronounced discrete frequency or pure tones. The broadband noise is a result of different forms of hydraulic noise, caused by turbulence and the effects of flow instability already discussed. The broadband noise is usually secondary in magnitude and related to poor pump design or applications, and on the intensity of turbulence, appearance of cavitation, or water hammer. Impact and roughness in bearings also produce broadband noise.

Discrete-frequency tones in the noise spectrum of a pump are provoked by interaction of the moving elements with nearby stationary or moving objects and appear at the rotational frequency $f_1 = n$ (n is the number of revolutions or strokes per second) and at the frequency $f_2 = inz_f$ (z_f is the number of impeller blades in the kinetic pumps or the number of compression or intermittent operation of piston or plunger or diaphragm in reciprocating pumps, or the number of pumping events per rotation at rotary pumps, for example, number of teeth, vanes, lobes and the like, and i is the harmonic number (1, 2, 3, ...), also called blade passage frequency (BPF) with kinetic pumps. In many cases, the first three harmonics of the f_1 and f_2 are predominant (see Fig. 5). Figure 5a shows the noise spectrum of a centrifugal pump without (thick curve) and with cavitation (thin curve).

With *reciprocating pumps* the impact source of noise is abrupt, therefore the noise spectrum contains major pronounced discrete-frequency tones typically dominated by fundamental frequencies and their higher (prominent 3 to 10 or more) harmonics. The fundamental frequency is defined by the number of strokes per second, whereas the amplitudes of the particular discrete-frequency tones depend on the stroke length. Figure 5b portrays the spectrum of a three-plunger pump with three pronounced spikes among them; the third represents the plunger frequency. Discrete frequency tones in a reciprocating pump may also be due to failures and damage of the piston ring and internal check valves.

With *rotary pumps*, discrete-frequency tones are provoked by fluctuating flow caused by teeth, vanes, screw and lobes, unbalanced rotating parts, misaligned parts, fluctuations in the load, failures and damage of

(a)

(b)

Figure 5 Noise spectra with tonal and turbulent noise: (a) for kinetic pump and (b) for piston pump.

displacement elements, impact between teeth at gear pumps, and so on.

Noise spectra of piping systems are usually also broadband in nature with pronounced discrete frequency tones. The broadband noise is a result of piping vibrations occurring by flow-induced pulsations in the piping system. Noise in pipe fittings such as dampers, elbows, and branch takeoffs and obstructions is also generally broadband and limited to a frequency range between 500 and 8000 Hz. Instability in the piping system, such as cavitation, flashing, and water hammer, also causes mostly broadband noise. The discrete-frequency tones in the piping system are a result of incoming noise produced by an operating pump, especially in the case of positive-displacement pumps and due to excited piping resonances. Among them only the first two resonance orders is worth examining: the first-order resonance or fundamental frequency and the second-order resonance or second harmonic. The resonant frequency depends on the distance between supporting places (the longer the distance, the lower the mode of vibration or resonances), and on the type of hanger or supporting elements.

7 EFFECTS OF PUMP TYPE, GEOMETRY, PRESSURE, SPEED, SIZE, AND MATERIALS

The magnitude and frequency of noise generated by a pump depend on the pump type, on its material,

geometry (size and form), and on the operating conditions (speed and load), that is, on the operation point on its characteristic curve. In general, total noise level increases by increasing the rotational speed and dimension, but the effect of load depends on the operating characteristics of the pump. With kinetic pumps, the flow rate can be changed from zero to the maximum flow rate or free delivery, with BEP in between. The noise characteristic depends on the operation point and has a minimum usually at the BEP (Fig. 2a, b). At off-design operation, noise level increases toward a zero flow rate and toward free delivery. With kinetic pumps with unstable characteristics, maximum noise level can appear at the surge point, which usually appears at a flow rate between 30 and 60% of the BEP for centrifugal pumps, and between 70 and 80% of the BEP for axial-flow pumps. According to Lips,¹⁰ by increasing pump power from 1 to 1000 kW, the sound power level increases by 40 dB (from 70 to 110 dB) for centrifugal pumps, and by 30 dB (from 80 to 110 dB) for axial-flow pumps.

With positive-displacement pumps, the flow characteristic is almost independent of load; the flow rate is nearly constant at different delivery pressures; therefore, the total noise level depends on the pump type and dimension (size or working volume), speed, and delivery pressure. Effect of the pump operating pressure, working volume and power consumption on the emitted sound power level is presented in Table 1.^{10,11}

Pump noise depends also on the material from which the pump was fabricated. Pumps fabricated from a rubber polyvinyl chloride (PVC), elastomer, composite, lead and coated steel housing, impeller, piston or screw by rubber, or Teflon (due to low friction also by glass, enamel, etc.) generate less noise than those fabricated from steel, cast or alloy steel, cast iron, and similar rigid material.

8 PREDICTION OF NOISE AND VIBRATION GENERATED BY PUMPS AND PIPING SYSTEMS

Noise and vibration generated by a pump and pumping system is difficult to predict due to numerous generating mechanisms that are changed by changing of the operation conditions. The total emitted noise consists of the pump noise and the piping system noise, both of them having fluid-borne and the structure-borne origins.

Equations for calculation of the A-weighted sound power levels in dependence on the power pump are given in Table 2 for different types of pumps.^{12,13} These equations are valid for a limited range of the power consumption within which the measurements were done, and by taking into account a certain degree of uncertainty, which is given in each equation.

Noise emission from piping systems having characteristics of a line source depends on the structure-borne noise generated in the piping and armature and on the

Table 1 Increase in A-weighted Sound Power Level of Pump by Increasing Operating Pressure, Working Volume, and Pump Power

Pump	Axial Piston Pump	Gear Pumps	Vane Rotary Pumps
Increasing of operating pressure from 20 to 300 bars	Up to 20 dB	Up to 10 dB	Up to 4 dB
Increasing of pump working volume from 5 to 250 m ³	Up to 30 dB	Up to 22 dB	Up to 4 dB
Increasing of pump power from 1 to 125 kW (see also Table 2)	Up to 25 dB (from 73 to 98 dB)	Up to 8 dB (from 76 to 84 dB) with outer teeth, and up to 20 dB (from 65 to 85 dB) with inner teeth	Up to 20 dB (from 72 to 92 dB)

Table 2 Prediction of the A-weighted Sound Power Level Generated by Different Pumps

Type of Pump	A-weighted Sound Power Level, (P in kW, $P_{\text{ref}} = 1$ kW) in dB	Valid for Power Consumption P
Centrifugal pumps (single stage)	$L_{\text{WA}} = 71 + 13.5 \log P \pm 7.5$	$4 \text{ kW} \leq P \leq 2,000 \text{ kW}$
Centrifugal pumps (multistage)	$L_{\text{WA}} = 83.5 + 8.5 \log P \pm 7.5$	$4 \text{ kW} \leq P \leq 20,000 \text{ kW}$
Axial-flow pumps	$L_{\text{WA}} = 78.5 + 10 \log P \pm 10$ at Q_{BEP} $L_{\text{WA}} = 21.5 + 10 \log P + 57Q/Q_{\text{BEP}} \pm 8$	$10 \text{ kW} \leq P \leq 1,300 \text{ kW}$ $0.77 \leq Q/Q_{\text{BEP}} \leq 1.25$
Multipiston pumps (inline)	$L_{\text{WA}} = 78 + 10 \log P \pm 6$	$1 \text{ kW} \leq P \leq 1,000 \text{ kW}$
Diaphragm pumps	$L_{\text{WA}} = 78 + 9 \log P \pm 6$	$1 \text{ kW} \leq P \leq 100 \text{ kW}$
Screw pumps	$L_{\text{WA}} = 78 + 11 \log P \pm 6$	$1 \text{ kW} \leq P \leq 100 \text{ kW}$
Gear pumps	$L_{\text{WA}} = 78 + 11 \log P \pm 3$	$1 \text{ kW} \leq P \leq 100 \text{ kW}$
Lobe pumps	$L_{\text{WA}} = 84 + 11 \log P \pm 5$	$1 \text{ kW} \leq P \leq 10 \text{ kW}$

fluid-borne noise generated by moving fluid in the piping system. Both of them depend on the type, size, and rotating speed of the pump built in the hydraulic system, on the pumping fluid characteristics and its velocity, temperature, and suspended rigid and gas particles in, then on, the dimension (length, diameter, and wall roughness), configuration and material of the piping system, and on the armatures built-in and their coupling to the pipe, as well as on the support of the pumping system and distances between fixings, and so on. Due to the complexity of the pumping system, only formulas for prediction of the total emitted noise from its particular components, excited by structure-borne noise or by fluid-borne noise, within the flowing fluid, pipe, and armature, or from the piping to the surrounding air are on disposal.

For prediction of the A-weighted sound power level of a straight piping to surrounding air excited by structure-borne noise the next formula can be used:¹⁰

$$L_{WA} = 10 \log(\overline{v^2}/v_0) + 10 \log(S/S_0) + 10 \log \sigma \quad \text{dB} \quad (1)$$

where $\overline{v^2}$ is the mean-squared vibration velocity measured on the piping wall (in m^2/s^2), v_0 is the reference velocity (1 m/s), S is the outer cross section of the pipeline ($\pi D^2/4$) (in m^2), S_0 is the reference surface 1 m^2 , and σ is the frequency-dependent radiation ratio, which can be estimated for a case without any pronounced discrete-frequency tones by next formula:

$$\sigma(f) \approx \frac{1}{1 + [c/(4Df)]} \quad (2)$$

where c is the speed of sound in the air around the pipeline (in m/s), f is the central frequency of the frequency band observed (in Hz), and D is the pipe outer diameter (in m).

For prediction of the internal A-weighted sound power level of the noise generated by the flow within straight pipeline with constant cross section, the next formula can be used:

$$L_{WA} = K + 10 \log(w/w_0) + 10 \log(S/S_0) + 10 \log(p/p_0) - \log(L/L_0) \quad \text{dB} \quad (3)$$

where $K = 8 - 0.16w$, w is the flow velocity within pipe (in m/s), $w_0 = 1$ m/s, S is the internal cross section of the pipe (in m^2), p is the sound pressure in fluid (in Pa), $p_0 = 10^5$ Pa, L is the pipe length (in m), and $L_0 = 1.4$ m.

This fluid-borne noise is heard outside the pipe but reduced for transmission loss in the pipe wall. The transmission loss depends on the material and geometry of the piping and can be calculated by^{10,14}

$$R_R = 9 + 10 \log \frac{\rho_w c_w s_w}{\rho_F c_F D_i} \quad \text{dB} \quad (4)$$

where ρ_w is the density of the pipe wall, ρ_F is the density of the flowing fluid, c_w is the speed of sound in the wall of the pipeline, c_F is the speed of sound in flowing fluid (in kg/m^3), s_w is the pipe wall thickness, and D_i is the internal diameter of the pipe.

An additional reduction in transmitted sound energy by fluid-filled circular pipeline wall can be expected, for a pipe diameter nearly equal to the wavelength, at the next (resonant) frequencies:

$$f_{D,n} = \kappa_n c_F / (\pi D_i) \quad \text{and} \quad f_R = c_L / (\pi D_i) \quad (5)$$

where $n = 1, 2, 3, \dots, 6$, $\kappa_n = 2D_i/\lambda_F$, λ_F is the wavelength in the flowing fluid.

Vibration of the hydraulic system also cannot be predicted by a common formula since there is a lot of excited forces and modes of vibration depending on the pump (its type, size, and speed) and on the piping system and its dimension and configuration. Therefore, there are only formulas for prediction of vibration for particular hydraulic system components, such as driving shaft of the pump, piping, and some armatures. Vibration energy from the pumping system is important below 100 Hz when resonances can cause large structural displacements and corresponding high stresses.

Vibration of drive shaft is a result of two independent forms of vibration, translational due to oscillation about its ideal "at rest" centerline and torsion due to the twisting of the shaft about the centerline. If the driving shaft is designed with torsion frequency well outside any exciting frequencies and so outside the torsion natural frequency, for more than 50% as usual case is, then torsion vibration of the shaft is not problematic. The translational vibration can be problematic especially in the case of a higher degree of unbalance. The lowest natural frequency due to translational vibration can be calculated for the drive shaft with circular cross section by

$$f_1 = \frac{\gamma_1^2 D}{8\pi L^2} \sqrt{\frac{E}{\rho}} \quad (6)$$

where f_1 is the first-order shaft resonance (in Hz), γ_1 is the coefficient of bending resonance, D is the diameter of the shaft (in mm), L is the effective length of the shaft (between both the driving and the driven ends) (in mm), E is the modulus of elasticity (in Pa), and ρ is the density of the shaft (in kg/m^3). According to Karasik and McGuire,¹ the average bearing housing vibration velocity for pumps with running speed between 1500 and 4500 rpm increases with pump speed to about the 0.33 power of the speed ratio. Usual vibration velocities are between 0.7 and 4.4, and up to 10 mm/s root mean squared (rms). Pumps with bearing housing vibration velocity below 2 mm/s rms are good, between 2 and 4 mm/s are acceptable, between 4 and 5.5 mm/s are poor, between 5.5 and 9 mm/s are schedule for repair, and above 9 mm/s rms has to be shutdown immediately.

Vibrations of the piping system occur in three most important natural modes of free vibration: compression, bending, and radial. Each of these modes occurs only at particular discrete frequencies, called resonant frequencies, which depend on the stiffness and the mass of the piping. The bending and radial modes are the most important since the pipe wall motion is perpendicular to the length of the pipe. The bending mode resonant frequencies for a straight piping system of uniform diameter and physical properties can be calculated by

$$f_n = \frac{\gamma_n^2}{2\pi L^2} \sqrt{\frac{EIg}{G}} \quad (7)$$

where f_n is the resonance frequency (in Hz), γ_n is the coefficient of bending resonance, L is the length of pipe between supports (in m), E is the modulus of elasticity (in Pa), I is the moment of inertia (in m⁴), g is the acceleration due to gravity (9.81 m/s²), and G is the weight (including fluid) per unit length (in N/m). Values for γ_n depend on the boundary conditions describing how the pipe is supported at the end of a pipe section (simply, anchored, or combination), and the order of the mode. For fundamental resonance its values are for a simply support 3.14, for anchored support is 4.73, and for combined support 3.93, and so on.¹⁵

Within a piping system there are also acoustic resonances caused by the running pump producing pressure pulsations. The natural acoustic resonant frequencies of a straight, uniform length of pipe open or closed at both ends can be calculated by

$$f_n = nc/2L \quad (8)$$

where n is the resonance order ($n = 1, 2, 3, \dots$), c is the wave propagation speed of fluid, and L is the length of the column of fluid between discontinuities where a reflection is anticipated.

9 NOISE CONTROL OF PUMPING SYSTEMS

Noise control of a hydraulic pumping system can be made at the source, transmission path, and at the receivers (listener). At the source, noise can be controlled by changing the pump operating condition or by modifying the basic pumping system design (by redesigning or changing the connection of assembled parts, by including different kind of dampers and silencers between the pump and piping system, etc.). On the transmission path, noise can be controlled by interrupting the path between the pumping system and listener, for example, by enclosing the pump and piping system or by erecting barriers between the pumping system and listener. At the receiver, noise can be reduced by physically enclosing the listener or by use of personal protecting equipment. Noise control by using barriers and by protecting the listener is beyond the scope of this section.

A hydraulic pumping system consists of a pump and piping system; therefore, we have to distinguish

between the noise control of the pump and pumping system. There are different methods for noise reduction. The most powerful is changing the operating point of the pump. The *operating point of the pump* can be changed by changing the rotational speed and load with kinetic and rotary pumps or by changing number and length of strokes with reciprocating pumps. The lower the rotational speed and number and length of strokes, the lower the noise and vice versa; however, the load should always be at or close to the BEP. With proper operating point and design, we also have to avoid the onset of cavitation in the pump. The operation point depends also on the pumping system characteristic or resistance curve, which depends on many parameters, such as dimension, configuration, and armature built-in. Therefore, modification of particular components or dimensions of a pumping system can change the operation point and is frequently an effective tool for noise reduction, although it can sometimes be also ineffective.

Noise control of a pump can be achieved by a reduction of rotating frequency, by modification or elimination of causes of hydrodynamic and mechanically generated noise. With kinetic pumps it can be achieved by changing the number and form of the impeller blades and diffuser or guide vanes. With centrifugal pumps, noise can be effectively reduced by changing (increasing) the radial clearance between impeller diameter and volute tongues or diffuser vanes (preferably 5 to 10% of impeller diameter); that is, by reducing the effect of BPF. The radial clearance can be increased by turning the impeller outer diameter or by grinding (reducing) the volute tongue, but in this case we must take into account that volumetric efficiency (and also the total efficiency and total delivery head) decreases. With positive-displacement pumps, noise can be reduced by increasing the number of pistons or plungers (preferably an odd number, nine at the most) to reduce pulsation of the delivery flow and pressure differences in the discharge vessel, by the exact closure of the inner valves at reciprocating pumps, by optimization of the number and form of rotating elements (teeth, screws, vanes, lobes), radial and axial clearances between rotating elements and casing, and by modification of the interaction of the components, which strike each other to produce the impact at rotary pumps.

The noise of positive-displacement pumps can also be reduced by modification of impact surfaces and time of impact (e.g., by using conical or ball valves instead of a plate type of inner valve plug), by replacing stiff, rigid materials with resilient materials (durable polymers and plastics instead of steel valves) at reciprocating pumps, by helical or spiral gear sets instead of spur or bevel gears, by finer pitches and shorter teeth, by improving gear lubrication, by introducing a soft material (such as lead, rubber, or plastic) in gear pumps and by using roller instead of plate types of vanes in vane rotary pumps.

The noise of a pump can be further reduced by use of journal-type instead of antifriction bearings, by replacement or adjustment of worn, loose, or

Figure 6 Methods for reduction of pressure pulsation in piping.

unbalanced parts of pump, by changing of the size, stiffness, or weight to change the resonance frequency, by flexible shaft couplings and mounts, by resilient flooring, by belts instead of gears for drives, by rubber or plastic bumpers or cushions (pads), by different pump models or types to permit operation at reduced speeds, and so on.

Noise generated by a pump is radiated to the surrounding air through the vibrations of the pump case, the pipe wall, or other structures to which the pump system is coupled by liquid or mechanical attachment. Therefore, pump noise can be reduced by enclosures, built in-line silencers or dampers, isolation mounts between the pump and the reservoir, by avoiding in-line mounting, and so on. The use of enclosures around a pump or piping system has the highest transmission loss, when its area density is high and is not mechanically tied to the vibrating surfaces of the pump. A total enclosure around a pump must have openings to prevent overheating, formation of explosive mixtures, and access for maintenance of the pump. Treating the interior of the enclosure with sound-absorbing material reduces the apparent source strength by preventing reverberant buildups in the enclosure.

Noise control of a piping system can be achieved by redesigning the piping system and/or by modification or interruption of the transmission path in the piping system, that is, from the pump to the radiating surfaces (piping). Redesigning the piping system is based on changing the size, form, and material of piping, by changing the form, number, and position of the built-in valves, T and Y approaches, dampers and silencers, and the supporting elements. Interruption of the transmission path can be achieved by reducing pressure pulsation in the pump's suction and discharge piping, by changing structural or natural frequencies of vibrating piping system, by built-in intake and exhaust damping elements, such as flexible sections in pipe runs (short lengths of flexible hose near the pump inlet and discharge), by the addition of damping to structural elements, for example, fabric sections in ducts with viscoelastic damping materials in the form of pipe lagging and wrapping materials, jackets made from absorptive materials of a heavy, solid, impervious skin of plaster, cement, metal, or mass-loaded vinyl, sacks of sand, thermal foil, mineral or fiber wool, and metal covers.

Reduction of pressure pulsation can be achieved by installing flexible connectors, by use of mufflers and dampers or expansion chambers, by acoustic filters or pulsation dampers (filled with liquid or air),

and by side-branch accumulators or tuned resonators (a closed-end tube attached to the main pipe), by the use of flexible couplings or compensators in the piping systems (rubber or metal compensators, flexible PVC, molded rubber, two layers of ribbed neoprene, fiberglass, nylon cord reinforcement, or a combination of these) and so on (see Fig. 6).

Structural vibrations or natural frequencies and their higher harmonics can be reduced or modified by dynamically balancing all rotating and oscillating components of the pump. To avoid shaft torsion vibration and resonances, the fundamental exciting frequencies must be at 50% below or above the natural frequency, and passing through the natural frequency range has to be as quick as possible. Structural vibrations can also be reduced by detuning, which implies changing either the driving frequency of the pump or the natural frequency of the piping system. These can be achieved by an increase of the stiffness or rigidity and weight of a radiating surface, that is, by changing the stiffness-to-weight ratio, or by raising or lowering natural frequencies by using dynamic absorbers or vibration isolators, that is, by attachment of a passive mass to a vibrating element or system with a resilient component, for example, a rubber, steel spring, pads, or slabs of resilient materials under the base plate (Fig. 7), by decoupling between a heavy, airtight outer coating and the vibrating pipe wall, or by mechanical isolation of the pumping system from the structure with vibration isolators (resilient pipe hangers and supports), by increasing the piping resonance frequencies above the highest machine frequency (by more than 50%), by avoiding rotational speeds that match or excite the natural or resonance frequencies of the translational vibration of the drive shaft, and by shifting the natural frequency to a higher frequency where human hearing is weaker and sound is more easily attenuated. Resilient elements may be inserted anywhere along the transmission path, but they are usually most effective near the source or near radiating surfaces.

The noise of control valves and radiation from the pipework can be reduced by lagging or burying of piping and valves, fitting multihole orifice plates in the line downstream from the valve to split the required pressure drop into several stages (each stage preferably having less than critical pressure drop), fitting in-line silencers downstream and possibly upstream of the valve in conjunction with lagging of the piping between valve and silencer, and fitting a low-noise control valve.

Figure 7 Methods for reduction of structural vibrations.

Cavitation in pumps can be controlled by raising the NPSH available value or the net inlet static pressure in the pump, which must be above the vapor pressure. The NPSH required can also be provided by replacing the existing pump or impeller with one that can operate with the existing NPSH, by a small axial-flow booster pump placed ahead of the first-stage impeller (driving on the lower rotation speed), by an inducer used as a first cascade of the whole inducer-centrifugal-impeller wheel, by lowering the liquid temperature, reducing the impeller speed, increasing the suction pipe diameter, decreasing the suction losses, simplifying the suction piping layout, injecting a small quantity of air into pump suction, which reduce also the cavitation curve, and so on.

Cavitation in the pumping system can be controlled by keeping pressure above the vapor pressure of the fluid being pumped, by reducing pressure pulsation, by burying the pipeline, by employment of adequate valve size, by reducing flow velocities without obstructions, by degasifying the fluid, by including cage-type valve trim for globe valves that moves the primary fluid restriction away from the valve plug seat line, and by two or more valves in series, each taking a portion of the total desired pressure reduction and so by preventing dropping pressure within the valve below the vapor pressure of the fluid, and so forth. Effect of cavitation can be prevented by using heavy-walled piping (which is subject to damage) and by furnishing hardened materials to increase resistance to cavitation. Cavitation noise can be reduced by applying acoustical insulation on the valve and associated piping, by installing the valve in an enclosure, and the like.

Water hammer in pump discharge lines can be reduced by starting a pump against a closed gate valve and then opening the valve slowly afterward, by stopping the pump after the valve has been fully closed (this method fails when a unit is stopped suddenly by control or power failure), by shutting the gate valve slowly, by increasing the size of the discharge line and lowering the flow velocity, by employing a

special protective valve (which opens wide quickly with the drop of pressure that is part of a water hammer cycle, and then closes slowly to throttle the resulting back flow), by further employment of air-charged surge tanks or shock-absorbing air chambers near the control valve, by lengthening the stopping time using a flywheel on the unit in a high-head installations, and so on.

CHAPTER 74

NOISE OF COMPRESSORS

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Compressors are used widely throughout the world in household appliances, air-conditioning systems, vehicles, and industry. Compressors are also used in health-care applications to provide air for dentists' drills and for breathing apparatus in hospitals. It is clear that control of noise and vibration is crucial in these applications. Various compressors are used for these applications, and there are a large number of quite different designs. The compressor design adopted for each application depends upon several factors, including the gas or working fluid that must be compressed and the discharge pressure and flow rates that need to be achieved. There are two basic types of compressors: (1) positive-displacement compressors including reciprocating piston and rotary types and (2) dynamic compressors including axial and centrifugal types. Positive-displacement compressors can be further subdivided by the location of the motor: (1) external-drive (open-type) compressors have a shaft or other moving part extending through the casing and are driven by an external power source, thus requiring a shaft seal or equivalent rubbing contact between fixed and moving parts, (2) hermetic compressors have the compressor and motor enclosed in the same housing shell without an external shaft or shaft seals and the motor operates in the compressed gas, and (3) semihermetic refrigerant compressors have the compressor directly coupled to an electric motor and contained within a gas-tight bolted casing and the motor operates in the compressed gas.

2 BACKGROUND

The noise generated by the piston type of compressor depends upon several factors, the most important being the reciprocating piston frequency and integer multiples, number of pistons, valve dynamics, and acoustical and structural resonances. The noise produced by the rotary types depends upon rotational frequency and multiples, numbers of rotating elements, flow capacity, and other flow factors. The noise generated by centrifugal and axial compressors also depends upon rotational frequency; the number of rotating compressor blade elements, flow speed, and volume flow rate, however, are also important factors. This chapter describes some design and operational features of several categories of commercially available gas compressors, noise and vibration sources and paths, and some examples of how noise and vibration problems have been overcome in practice.

Compressors can be considered to be pumps for gases. (See Chapter 73 on pumps.) Although there are some differences in construction details between compressors and pumps, their principles of operation are essentially the same. Since gases normally have much lower densities than liquids, it is possible to operate compressors at much higher speeds than pumps. However, gases have lower viscosities than most liquids, so leakage with compressors is more of a problem than with pumps. Thus, this requires tighter manufacturing tolerances in the moving parts of compressors. The mechanical action of the compressor causes the gas volume to decrease and a considerable amount of work done on the gas usually is turned into heat. There is a necessity to cool the gas sufficiently; otherwise overheating can occur resulting in excessive wear and compressor failure. To achieve large pressure rises, compression can be done in successive stages, with cooling applied between the stages. Compressors are usually classified as either of two basic types: (1) positive-displacement or (2) dynamic machine types.

Positive-displacement compressors increase the pressure of the gas by reducing its volume in a compression chamber through work applied to the compressor mechanism. Positive displacement compressor mechanisms can be further subdivided into: (1) reciprocating types: piston, diaphragm, or membrane and (2) rotary types: rolling piston, rotary vane, single-screw, twin-screw, scroll, and throchoidal (lobe.) Figure 1 presents a schematic of the main types of positive-displacement compressors. Dynamic compressors increase the pressure of the gas by a continuous transfer of angular momentum from the rotating machine components to the gas. This process is followed by the conversion of this momentum into a pressure rise. Dynamic compressors can be divided into (1) centrifugal, (2) axial, and (3) ejector types. Figure 2 provides a schematic of the main types of dynamic compressors.

3 COMPARISON OF PERFORMANCE AND CAPABILITIES OF VARIOUS COMPRESSOR TYPES

Positive-displacement compressors are normally used for small volumetric flow rate capacity requirements such as in household refrigerators or room air conditioners. For higher flow rate capacities, valve and seal leakage, mechanical friction, and flow effects quickly decrease the efficiency of positive-displacement compressors.

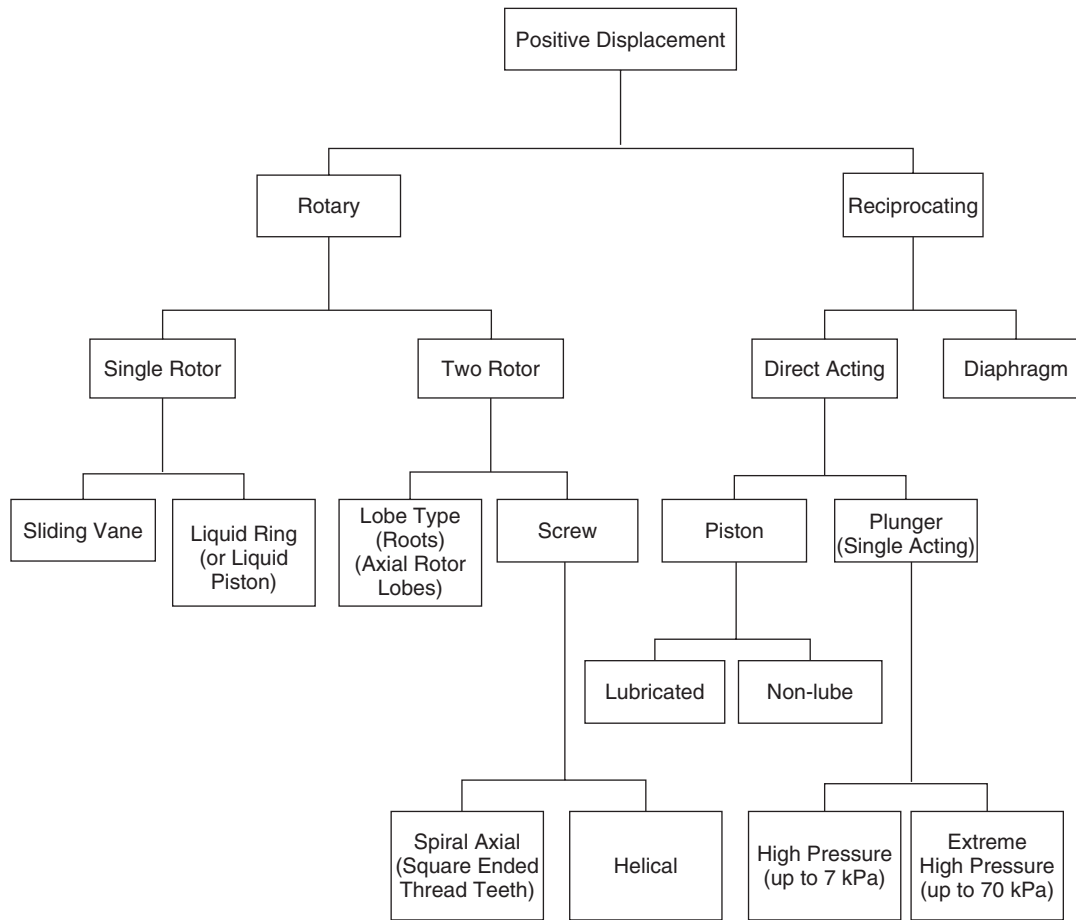

Figure 1 Schematic showing types of positive-displacement compressors.¹

Centrifugal compressors generally have higher efficiencies than positive-displacement types and can provide higher volumetric flow rates. Centrifugal compressors are unsuitable for small flow rate capacities. The sealing surface is large for a centrifugal compressor compared to the compressor element, and the rotating impeller surface area. However, as the compressor size is increased, to achieve higher flow rate capacities the sealing surface losses increase much more slowly than the impeller area, which leads to improved overall efficiencies.

Axial compressors achieve the highest overall efficiencies when high flow rate capacities are required. The mechanical and fluid mechanics losses are small for axial compressors and efficiencies can be as high as 90% or more. Axial compressors also have the highest flow rate capacities for a given volumetric size. Axial compressors can thus be made compact and lightweight, which explains why they are favored for use in aircraft jet engines. Continual design improvements over the years have resulted in higher efficiencies.

Dynamic compressors create the increase in discharge pressure by adding kinetic energy to a continuously moving fluid flow. The fluid streamlines through the rotating blades of an axial compressor are gently curved with a fairly large radius. The streamlines in a centrifugal compressor, however, are extremely curved and undergo considerable changes in radius and cross-sectional flow area, resulting in subsequent area reduction. For that reason, the centrifugal compressor can achieve a much greater pressure ratio per stage than an axial-flow compressor; but an axial-flow compressor can achieve a much greater volume flow rate than a centrifugal compressor for the same frontal area. An axial-flow compressor behaves almost like a variable pressure ratio, constant flow rate machine, while a centrifugal compressor behaves almost like a constant pressure ratio, variable flow rate machine.

Table 1 presents a comparison of some of the advantages and disadvantages of different compressor designs.

Figure 2 Schematic showing types of dynamic compressors.¹

Table 1 Advantages and Disadvantages of Different Compressor Designs

Type	Advantages	Disadvantages
Positive displacement	Pressure ratio capability affected by gas properties	Limited capacity
Centrifugal	Good efficiencies at low specific speeds Wide operating range Low maintenance High reliability	High weight-to-capacity ratio Unstable at low flow Moderate efficiency
Axial	High efficiency High-speed capability Higher flow for given size	Low-pressure ratio per stage Narrow flow range Fragile and expensive blading
Ejector	Simple design Inexpensive No moving parts High-pressure ratio	Low efficiency Requires high-pressure source

4 POSITIVE-DISPLACEMENT COMPRESSORS

This section provides brief descriptions and simplified diagrams of the main operating features of commonly used positive-displacement compressors. For more extensive construction and operating details, and the advantages and disadvantages of each compressor type, the reader is referred to specialized books on compressor design and operation.¹⁻⁸

4.1 Reciprocating Piston Compressors

The reciprocating compressor was the first type designed for mass production. It still sees service in a wide variety of industrial and household applications, and it remains the most versatile compressor design. It can operate economically to produce very small pressure changes in the deep vacuum range up to very high pressures of the order of 150,000 to 450,000 kPa, for example, in a chemical polyethylene plant service. Figure 3 shows the principle of operation of a reciprocating piston compressor.

The operation of a reciprocating piston compressor is in many ways similar to that of an internal combustion engine, although the design of such small compressors is simpler. Small reciprocating compressors are the units often chosen for operation in household refrigerators and heat pumps. The mechanical system of a typical small refrigerator reciprocating compressor is comprised of an electric motor driving a reciprocating piston axially in a cylinder to change the gas volume. Two thin metal "reed" valves are provided. As the piston moves to compress the working gas during the compression stroke, the suction valve closes and the discharge valve opens. After the piston has reached top dead center, and it begins the suction stroke, the suction valve opens and the discharge valve closes.

4.2 Diaphragm Compressors

Diaphragm compressors, such as shown in Fig. 4, are a form of piston compressor. The diaphragm separates

Figure 3 Reciprocating piston compressor.

Figure 4 Vibrating diaphragm compressor.⁸

the gas undergoing compression on one side from the hydraulic working fluid on the other side. A piston is provided to force the hydraulic fluid upward; it is commonly driven by an electric motor via a connecting rod, which is eccentrically connected to the motor drive shaft. As the piston moves up, it displaces the incompressible hydraulic fluid upward making the diaphragm move up also. The membrane is sandwiched between two perforated metal plates that allow hydraulic fluid to flow through the perforations in the lower plate and gas to flow through the perforations in the upper plate. When the piston is at top dead center, the diaphragm is pressed hard against the underside of the top plate by the hydraulic fluid and the discharge valve has already opened but is ready to start closing. On the piston down stroke, the diaphragm is drawn downward, thus allowing the intake valve to open and a fresh charge of gas to enter above the diaphragm ready to be compressed on the next upward stroke of the piston.

Diaphragm compressors are often used where very low flow rates of the order of 0.03 to 3.0 m³/minute and pressures of the order of 10×10^6 to 500×10^6 Pa, are needed, or where it is necessary to keep the gas or corrosive fluid to be compressed out of contact with the piston and its lubricating oil. One example is where oxygen is being compressed. In such cases, contact between oxygen and the piston's lubricating oil could be dangerous. In some cases, such as with oxygen compression, soapy water is used instead of oil as the hydraulic working fluid to lessen the chance of hazardous contact between the oxygen gas and flammable oil. For higher flow rates of 3.0 m³/min and above, the diaphragm compressor has limited application since use of a larger stroke of the diaphragm is needed, which can lead to diaphragm fatigue and eventual failure. For larger flow rates, either reciprocating piston compressors or rotary compressors are normally used.

4.3 Screw Compressors

Screw compressors are formed by the intermeshing action of two helical rotors. See Fig. 5. The rotors

are comprised of two types: male and female. The male rotors have convex lobes and the female rotors have convex flutes. The gas to be compressed enters through the inlet port and is trapped by the rotors, which continually reduce the volume available to the gas until it is expelled through the discharge port. A typical screw compressor has four lobes on the male rotor and six flutes on the female rotor. In such an arrangement the compressor has six compression cycles during each revolution of the female rotor, which is operated at two thirds of the male rotor speed. Screw compressors are normally chosen for flow capacity rates greater than those delivered efficiently by reciprocating compressors, but less than those delivered efficiently by centrifugal compressors. In this mid-flow rate range, centrifugal compressors tend to be large and thus very heavy and are normally less efficient than screw compressors in this range.

Screw compressors have the advantages that they are (1) lighter and more compact than reciprocating compressors, (2) do not have reciprocating masses requiring expensive vibration isolation, and (3) the rotors can be operated in a dry condition without the need for oil lubrication. Their main disadvantages include the fact that they have rapid rotor wear when operated in a dry state and that they are inherently very noisy. Oil is sometimes used as a lubricant to reduce wear and the use of water as a lubricant is under development.

4.4 Lobe or "Roots" Compressors

Figure 6 shows one of the oldest and simplest designs of compressor, known as a straight lobe or "roots" compressor. This type of compressor normally employs two identical cast-iron rotors. Each rotor has a figure eight shape with two rounded lobes. As the rotors turn they sweep the gas into a constant volume between the rotors and the compressor case wall. Compression takes place as the discharge port becomes uncovered. Initially backflow occurs from

Figure 6 Lobe or roots compressor.⁸

the discharge line into the casing cavity, until the cavity pressure reaches the compressed gas pressure. The gas flow then reverses direction, and further rotation of the rotors causes increasing gas pressure with a reducing gas volume as the gas is then swept into the discharge line. Lobe or roots compressors have the advantage of being low cost and needing low maintenance. They have the disadvantage that they (1) are less efficient than screw or centrifugal compressors, (2) only achieve low pressure increases, and (3) are inherently noisy because of the high-frequency flow reversal that occurs at the discharge port.

4.5 Sliding Vane Compressors

The sliding vane compressor consists of a rotor mounted in an eccentric casing. Nonmetallic sliding vanes are fitted to the rotor in slots as shown in Fig. 7. The vanes are held in contact with the casing by centrifugal force. In Fig. 7 the gas is taken in from the suction inlet on the left side and discharged through the port to the right. The gas is trapped and sucked into volumes that increase with vane rotation up to top dead center.

The trapped gas is then compressed as the trapped gas volume continually decreases after top dead center. There are no inlet and discharge valves. The times at which the inlet and discharge ports are open are determined by the time when the vanes are located over the ports. The inlet port is designed to admit gas until the gas "pocket" between the two vanes is largest. The port closes when the second vane of that pocket passes the inlet port. The gas pocket volume is decreased when the vanes have passed the top dead center and compression of the gas continues until the discharge port is opened when the leading vane of the pocket passes over the discharge port opening. The discharge port closes when the second valve passes the end of the port.

Figure 5 Screw compressor.⁸

Figure 7 Sliding vane compressor.⁸

4.6 Rolling Piston Compressors

Rolling piston rotary compressors are widely used because they are small in size, lightweight, and efficient. Small rolling piston rotary compressors are often driven by electric motors. The rolling piston is contained in a cylinder, and the piston is connected to a crankshaft eccentrically mounted to the drive shaft of the motor. See Fig. 8. The stator of the electric motor is normally fixed to the interior of a hermetic shell. A spring-mounted sliding vane is provided. As the piston rotates inside the cylinder, the volume of gas trapped ahead of the piston—between the piston, cylinder, and vane—is reduced and the gas is expelled through the discharge. Simultaneously, gas is sucked into the increasing volume following the piston. After the piston has passed top dead center and the inlet (at the left side of Fig. 8), the volume of trapped gas ahead of the piston is decreased again as the piston moves further toward the discharge valve and the compression cycle is repeated.

4.7 Orbital Compressors

High-efficiency and high-performance refrigeration and air-conditioning systems are in great demand. So-called orbital compressors have many good characteristics such as high efficiency, good reliability, and low noise and vibration. A common type of orbital

compressor, is the scroll compressor which uses two interlocking, spiral-shaped scroll members to compress refrigerant vapor.^{9,10} Such compressors are now in common use in residential and industrial buildings for air-conditioning and heat-pump applications and also for automotive air conditioners. They have high efficiency and low noise but have poor performance if operated at low suction pressures and they need good lubrication. Scroll compressors normally have a pair of matched interlocking parts, one of which is held fixed and the other made to perform an orbital path. Contact between the two scrolls happens along the flanks of the scrolls, and in the process a pocket of gas is trapped and progressively reduced in volume during the rotary motion until it is expelled through the discharge port. Most scroll compressors are hermetically sealed inside a shell casing. Another type of orbital compressor is the so-called trochoidal type. The well-known Wankel design has a three-sided epitrochoidal piston with a two-envelope cylinder casing.^{9,10}

5 DYNAMIC COMPRESSORS

Centrifugal and axial compressors are used when high gas flow rates are required. They can be made to be of low weight and generally have higher efficiencies than positive-displacement types. Their operational principles are very similar to fans. See Chapter 71 for discussion of fan types, principles of operation, and noise generation mechanisms.

5.1 Centrifugal Compressors

Centrifugal compressors are widely used in large buildings, offices, factories, and industrial plants that require large central air-conditioning and cooling systems.¹⁻⁶ Such centrifugal compressors eliminate the need for valves. The number of parts with sliding contact and close clearances are reduced, compared with positive-displacement types. Thus maintenance costs are reduced, although operating costs may be increased due to their somewhat lower efficiency than comparable positive-displacement compressors. They are smaller and lighter in weight, and generally have lower original equipment and installation costs than equivalent reciprocating types. The noise and vibration characteristics are quite different, however,

Figure 8 Rolling cylinder compressor.

due to the higher speed and the lack of out-of-balance machine parts. The main components of a centrifugal compressor include (1) an inlet guide vane, (2) an impeller, (3) a diffuser, and (4) a volute.

5.2 Axial Compressors

Axial and centrifugal compressors are competitive for volume flow rates from about 25 to 90 m³/s, but when volume flow rates higher than about 60 m³/s are needed, axial-flow compressors are normally used instead of centrifugal-flow machines.³ This is because they are more efficient, smaller in size and weight, and require lower installation costs. They have several disadvantages, however, including generally more complex control systems, a narrower range of available flow rates, and surge and ingestion protection requirements. They also produce higher noise levels than centrifugal types, thus requiring more extensive acoustical treatment. Currently, axial compressors have their greatest use in aircraft and air transportation systems.

5.3 Ejector Compressors

The ejector compressor is the simplest form of dynamic compressor.^{1,4} It has no moving parts and is thus low cost. It is inexpensive, but has a low efficiency, however, and thus sees use mostly for vacuum applications. It requires a high-pressure source and transfers the momentum of the high-pressure jet stream to the low-pressure process gas.

6 NOISE CONTROL OF POSITIVE-DISPLACEMENT COMPRESSORS

It is normal to classify noise problems in terms of the source-path-receiver framework. In the case of compressors, it is not always so easy to make a distinct division between sources and paths. With positive-displacement compressors, the main noise source is the time-varying pressure pulsations created between the suction (inlet) and discharge manifolds of the compressor. This fluctuating pressure forces the compressor casing and any connecting structures into vibration, which consequently results in sound radiation. Many compressors have housing shell structures, and it is normal to vibration isolate the compressor casing from the compressor shell housing, which itself may or may not be completely hermetically sealed. Suction and discharge piping must be provided, and care must be taken to reduce vibration transmission paths from the casing to the shell housing through this piping. It is not possible to completely eliminate the vibration transmission through the compressor vibration isolation system, and the piping and the gas between the casing and housing also provides another path for sound energy transmission to the shell.

6.1 Compressor Valves

Positive-displacement compressors must be provided with valves to allow the transfer of the low- and high-pressure gas to and from the compressor. There are two

main types of valves: (1) demand valves and (2) gate valves.

6.1.1 Demand Valves Demand valves are designed to open only when the compressor pressure conditions require them to do so. In the case of the discharge valve, this is when the cylinder pressure exceeds the discharge manifold pressure, and in the case of the suction valve, when the cylinder pressure is less than the suction manifold pressure. Demand valves are normally provided with spring mechanisms to ensure that the valves stay closed during the required parts of the compression cycle process. The spring force can be produced by the bending force in the case of reed valves or by the provision of a coil or another type of spring in the case of some plate or poppet valves. Unfortunately, such valves tend to flutter, which introduces additional pressure modulations onto the already time-varying compressor pressure fluctuations. Such flutter-induced fluid pressure modulations result in additional compressor noise. Valve flutter is thus normally suppressed where possible to reduce this noise but also to try to prevent valve vibration and the possibility of valve fatigue and failure during service.

Valve flutter is a feedback mechanism and there are two main types. First, when the valve opens, it happens in an impulsive manner so that its natural frequencies of vibration are excited and the fluttering process is initiated. The flutter frequency is usually close to the natural frequency of the valve. The second mechanism is related to the Bernoulli effect. A negative pressure may be created in the discharge valve seat, which causes a delay in its opening.¹¹⁻¹³ When opening does occur, the valve can overshoot its equilibrium position and shut again before discharge is complete, and the cycle can be repeated. Structural damping of the valve motion has been found to have only limited effectiveness in reducing flutter. Flutter can, however, be reduced and sometimes almost eliminated by use of a motion limiter. However, the valve will hit the limiter and thus cause impact noise. When the valve closes again, it also causes impact noise as it hits the valve seat. Some attempts have been made to reduce motion limiter and valve seat impact noise by using soft materials. But success in using soft materials is limited because of the need to ensure sufficient material durability and proper sealing after valve closure.

6.1.2 Gate Valves Gate valves open and close during certain parts of the compressor cycle. They are used on rotary vane, screw, and scroll compressors. Gate valves have the advantage that reeds or plate valves are not needed, and so the flutter problems of demand valves are avoided. But gate valves are less efficient than demand valves since their opening and closing cannot easily be adjusted for different suction and discharge pressure requirements. Also gate valves suffer from their own noise problems. The fluctuating pressure caused by the opening and closing of the valves is periodic but not purely simple harmonic, so that in addition to a fundamental frequency, harmonics

are created. In addition, the sudden pressure increase at the opening of the discharge valve excites the natural frequencies of the discharge manifold gas. A similar situation exists at the suction valve with the suction manifold.

6.2 Manifold Mufflers

To try to reduce periodic pressure fluctuations from the discharge and suction valves propagating along the piping, discharge and suction mufflers are normally used. The simplest compressor muffler works as a Helmholtz resonator. For example, in the case of the discharge valve, a flow-through Helmholtz resonator design is sometimes used for the discharge muffler. In this case, the volume of the discharge manifold gas, which is located directly after the discharge valve, acts as the resonator spring. The neck of the Helmholtz resonator is usually formed by the short pipe or passage that opens into a second volume, known as the decoupling volume, which in turn empties into the discharge pipe.^{11–13} Simple suction mufflers can also be designed using Helmholtz resonator principles. In the case of a hermetically sealed compressor, the manifold volume in front of the suction valve can be made to act as the volume spring. The resonator neck can be formed by the narrow passage or short pipe that connects to the suction gas in the volume between the hermetic shell and the compressor casing.

The behavior of a flow-through Helmholtz muffler is similar to a forced mass–spring–damper system (see Fig. 10 in Chapter 1 or Fig. 4 in Chapter 54). The Helmholtz muffler behaves like a low-pass filter. Well below its natural frequency, the muffler is transparent to sound waves passing through. At and near its natural frequency, it actually amplifies the sound. At frequencies above the square root of two times its natural frequency, it attenuates the sound transmitted. More complicated mufflers can be built with a cascade of pass-through Helmholtz muffler systems. In such a cascaded system, the gas volumes will act as the springs and the connecting pipes as the Helmholtz resonator necks. The volumes and necks can be adjusted to have different natural frequencies. Side-branch Helmholtz mufflers can also be used, which attenuate sound at their natural frequencies. If the connecting pipes and the gas volumes used become long in terms of wavelengths (i.e., at high frequency), then the pipes should no longer be assumed to act as noncompressible masslike elements, and the volumes as simple springs.^{11–13} The attenuation characteristics of such muffler systems need to be analyzed with numerical approaches such as finite element or boundary element methods.

6.3 Gas Chamber Pressure Pulsations

As discussed, gas chamber pressure pulsations will occur at the *forcing frequencies* created by the compressor pumping frequencies and harmonic multiples. Gas volumes will have their own *natural frequencies*. If the forcing frequencies coincide with the natural frequencies, then resonance occurs. It is desirable to try to

avoid resonance conditions since gas resonances will excite the casing and shell (if present) into vibration. It must be remembered that the gas volume natural frequencies are temperature dependent. So that after the compressor has “warmed up,” the frequencies will change and they may also change as the valves open and close and other volumes become interconnected. The volume and temperature of the gas above the piston in the case of reciprocating compressors also change with time, thus causing the natural frequencies to vary with time. So it is not always possible to avoid gas resonance and coincidence with structural resonance for all compressor operating speeds and pressure conditions.¹³ Unless the volumes are simple axisymmetrical shapes, their natural frequencies and mode shape characteristics need to be analyzed with numerical approaches such as finite element or boundary element methods. See Chapters 7 and 8.

6.4 Casing, Piping, and Shell Vibration and Sound Radiation

For the purposes of the discussion here, the compressor casing is defined as the structure containing the piston or rotating compressor elements but excluding the piping and external shell housing. Because of geometrical complexities, the casing and shell natural frequencies and mode shapes have to be calculated with three-dimensional finite element models (FEM). The natural frequencies of small reciprocating compressor casings are usually quite high, on the order of 2000 Hz and higher.^{11–13} Shell natural frequencies are usually somewhat lower, on the order of 1200 Hz and above, since the shells are usually made of thinner metal and are larger in size than the casings. The sound radiation from the shell can be calculated using the boundary element method (BEM), provided the normal surface velocity distribution has been calculated using FEM, or it has been measured experimentally. If viscous damping materials are used to reduce shell vibration at the elevated shell temperature, and consequently to reduce the sound radiation as well, the materials selected must be chosen to have the maximum damping value at the compressor shell operating temperature.

The suction and discharge piping is connected to the compressor casing, and in the case of hermetic compressors it is usually soldered to the shell. It can act as a direct short-circuit transmission path for vibration from the compressor casing to the shell housing. Some attempts have been made to vibration isolate the piping from the casing and/or shell by the use of flexible materials. Unfortunately, such materials are not compatible with the working fluid and/or oil and are not durable enough. The tubing is usually bent, and since it is slender it has a large number of natural frequencies in the range from about 100 to 5000 Hz. Some attempts have been made to reduce vibration transmission along the tubes by damping them with wire spring, which is wound around the tubes. It is thought that this system provides vibration damping by impacts between the wire and tubes.¹⁴

7 CASE HISTORIES OF NOISE CONTROL OF POSITIVE-DISPLACEMENT COMPRESSORS

7.1 Noise Control of Small Reciprocating Piston Compressors

Webb was one of the first to write about noise control of small reciprocating piston refrigeration compressors in 1957.¹⁵ Since then many other authors have discussed their noise and vibration sources and methods of noise control.^{16–35} All of the main sources of noise in a small reciprocating compressor originate from the compression process. The sources include: (1) gas flow pulsations through the inlet and discharge valves and pipes, (2) gas flow fluctuations in the shell cavity, which excite the cavity and shell modes, (3) turbulent eddy formation in the shell cavity and inlet and exhaust pipes, (4) vibrations caused by the mechanical system rotation of the drive shaft and out-of-balance reciprocating motion of the piston and connecting rod, and (5) impulsive motion of the valves and impacts they cause. Electric motors are the normal power sources. In refrigeration compressors, noise and vibration are transmitted from the sources in four main ways: (1) a low-pressure refrigerant gas path, (2) a high-pressure discharge tube path, (3) external and internal suspension system paths, and (4) lubricating oil path. All four paths contribute directly or indirectly to the compressor shell vibration response and result in shell sound radiation,

Figure 9 gives a detailed cut-away drawing of a typical reciprocating piston compressor. With such a reciprocating piston system, impulsive noise is created by mechanical impacts caused by rapid closure of the suction and discharge valves. In addition, since the fit of the piston in its cylinder is not perfect, and a small amount of clearance must be provided, the gas forces on it caused by compression make it “rock” from side to side resulting in impacts known as “piston slap.” This is another potential source of radiated noise. Blow-by noise caused by gas escaping

through the piston/cylinder clearance can sometimes also be important. Although steady nonturbulent flow, in principle, does not cause the creation of sound waves, fluctuating flow does, and impulsive flow changes caused by the rapid opening and closing of the suction and discharge valves is responsible for the creation of sound waves that propagate throughout the inlet and discharge pipe work. The mechanical system is normally hermetically sealed in a compressor shell. Such compressors are expected to have a long operating life of at least 10 years.

Figure 10 presents a schematic of the main noise and vibration sources in a reciprocating piston compressor used in household refrigerators, air conditioners, and heat pumps. In many such compressors, the noise and vibration sources are strongly correlated (interrelated), and it is difficult to separate them.^{15–17} In a typical household refrigerator, besides the airborne noise radiated from the compressor shell, airborne noise is also produced by the cooling fan, flow-induced noise of the refrigerator, and structure-borne noise caused by all of these sources, which is then radiated as airborne noise by the refrigerator itself. Thus, to study the compressor noise experimentally, it is necessary to remove the compressor from the refrigerator and mount it in a load stand that provides the compressor with the correct refrigerant and pressure conditions. The load stand noise sources are separated from the compressor noise stand in well-designed experiments.^{15–17}

7.1.1 Vibration and Noise Measurements on Reciprocating Piston Compressors Figure 11 shows an example of the setup for vibration and noise measurements conducted on a small reciprocating piston compressor.³⁴

Figure 12 presents measured time-history results obtained with the setup in Fig. 11. It is observed that there is no obvious close correlation between the compressor body vibration (V_1) and the low-frequency

Figure 9 Vertical cut through a typical oscillating piston refrigerator compressor.³³

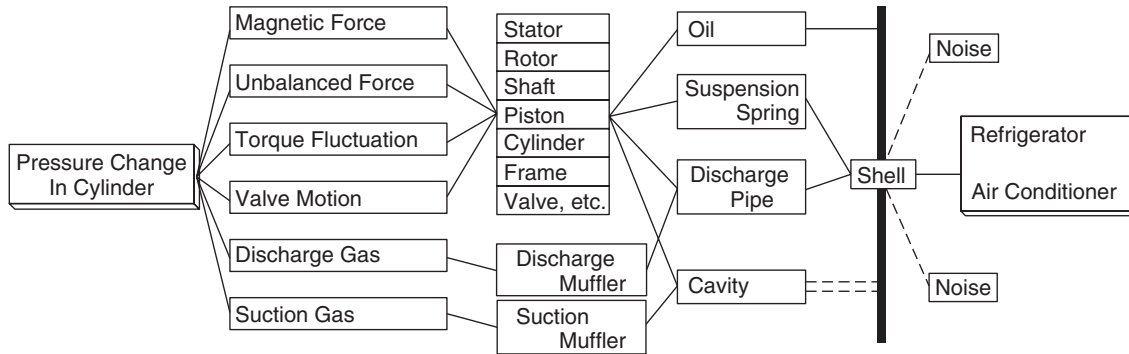

Figure 10 Schematic noise generation mechanisms in a reciprocating piston compressor driven by an electric motor.¹⁷

Figure 11 Measurements of the suction and discharge pressure fluctuations and valve motion on a reciprocating compressor; D_1 encoder gap measurement with displacement gauge using shaft signal; D_2 strain gauge measurement of suction reed valve to give valve motion.³⁴

sound pressure (noise) (P_4). The compressor working fluid has a discrete-frequency component of 240 Hz in the discharge pressure and of 480 Hz in the suction pressure. In such a compressor, modification of the fluid path volumes and pipe diameters to ensure that none of these frequency components match with the shell cavity volume natural frequency normally helps to reduce the low-frequency compressor noise in the range of 25 to 1000 Hz. The fundamental acoustic natural frequency of the cavity depends on its temperature of operation and will always be excited momentarily if the excitation frequency passes through

this natural frequency during compressor startup and/or shutdown.

7.1.2 Improved Design of Suction Muffler

Other methods of noise control include improved suction muffler design. Figure 9 shows a section through a typical refrigerator compressor.³³ In this design, the compressor pump unit consists of a piston–cylinder block that is mounted on top of an electric motor. The compressor pump–motor unit is enclosed in a 3-mm-thick hermetic steel shell, which together with the suction and discharge lines connects

Figure 12 Experimental results for compressor discharge pressures, valve suction motion and body vibrations, and sound pressure; P_1 suction muffler inlet pressure, P_2 suction outlet base pressure, and P_3 cylinder head (discharge plenum) pressure.³⁴

the unit with the appliance.³³ The suction chamber and its muffler can be seen at the top right of Fig. 9.

A cut-through view of the muffler is given in Fig. 13a and of a BEM model of it in Fig. 13b. When the compressor was operated under appliance conditions, it was observed that the sound power increased in the 800-Hz, 3.2-kHz, and 4-kHz one-third octave bands. Separate experiments on the compressor showed that the dominating source of noise in these bands is caused by the suction valve.³³ Pressure pulsations near to the inlet of the suction valve were thought to excite cavity modes. The lowest cavity modal resonance frequencies are at about 620 Hz and 720 Hz, and they have associated sound pressure distributions that are favorable at exciting deformed (breathing) modes of the hermetic shell. Unfortunately, these shell vibrations have rather high radiation efficiencies. These cavity resonances were assumed to be responsible for the relatively high sound power levels particularly in the 630 Hz and 800 Hz one-third octave bands.

Two other resonance frequencies were found to be very important with this compressor. These are the shell vibration natural frequencies of 2970 and 3330 Hz. These presumably are responsible for the high sound power levels in the 3.2-kHz one-third octave band seen in Fig. 15. The original suction muffler used in this compressor possesses two chambers connected in series by the inlet and the flow guide tube. See Figs. 13a and 13b. Figure 13c shows a schematic diagram of the model that was used to analyze the insertion loss of the suction muffler system.

The insertion losses (IL) measured and predicted using a BEM model are shown in Fig. 14a. It is observed that there is very good agreement up to a frequency of almost 2000 Hz. Above that frequency, the prediction is not so accurate, presumably because the BEM mesh size used was not small enough. The BEM program used to predict the IL was run changing

two variables U and V (see Fig. 13c). By increasing the slit between the inlet suction tube and the flow guide tube from 2.4 to 4.8 mm and moving the bent portion of the flow guide tube 1.4 mm in the direction of the arrow (see Fig. 13c) BEM predictions showed that the muffler insertion loss was improved. This is shown in the predictions in Fig. 14b. Finally Fig. 15 presents the measured sound power levels radiated before and after these design changes were incorporated in the real muffler and compressor. The sound power radiated at the four resonances 620 Hz, 720 Hz, 2970 Hz, and 3300 Hz is reduced. The sound power level of the unit was measured in both standard operating conditions as specified by the suction and discharge pressures (suction 0.6 bar and discharge 7.7 bar) and in the appliance operating conditions (suction 1.1 bar and discharge 6.0 bar) for the cooling medium (R600a).

From Fig. 14b, the BEM calculations predicted a reduction in noise of 9 dB at 3.2 kHz. The sound power measurements in Fig. 15, however, show a reduction of 13 dB at that frequency. Subsequent measurements revealed an even greater reduction of 23 dB.

7.1.3 Reed Valve Vibration and Noise The compression process in reciprocating compressors is controlled by suction and discharge valves. These are very often constructed as cantilever beams that impact the valve stops and seats and thus may be excited at their own natural frequencies. An oscillating discharge valve, for example, may cause a 130-N to 180-N oscillating force on the piston and a resulting vibration of the compressor structure.

In one case, the reduction of the noise of a reciprocating compressor was achieved by modification of the piston cylinder head and valves.³⁵ Figure 16a shows a schematic of a standard compressor cylinder head, piston, and valves before modification, and Fig. 16b

Figure 13 (a) Suction muffler cut-through drawing, (b) boundary element model (BEM)³³ and (c) diagram of original muffler; gray thick lines show which structural items were modified geometrically.³³

shows the same compressor parts after modification. The modified compressor had a Mota-compressor-clearance tap (MCCT) piston and suction valve as shown. The MCCT piston is seen to have a small “tap” attached to its upper surface that is made to fit into the discharge port when the piston reaches top dead center of its stroke. With the use of the tap the new piston assembly reduces the clearance volume when the piston is at top dead center, and this prevents back flow occurring during the suction stage, thus permitting the use of thinner suction and discharge “reed” valves. Use of the thinner reed valves changes the suction and discharge process and reduces the valve impact excitation and resulting compressor vibration response. It was found that these changes produced reductions of 3 dB in both the suction and discharge space-averaged externally radiated A-weighted sound pressure levels.

7.1.4 Shell Vibration The hermetic compressor shell is a closed shell usually consisting of a cylindrical part of circular or nearly elliptical cross section with domed heads at each end. The end heads usually have

more bending resistance than the cylindrical sides since they have curvature in two directions, and as such the cylindrical sides normally make the major contribution to the sound radiation.

The noise radiated by the compressor of a household refrigerator is mostly contributed by the noise radiated by the compressor shell. Many attempts have been made to study and understand compressor shell radiation from small compressors.³¹ There are three noise paths to the shell in an operating hermetic compressor: (1) forces are transmitted to the shell by the bracket springs used for the mounting of the compressor inside the shell (structure path), (2) suction and discharge tubing for the Freon or other working gas in the cavities in between the compressor and internal surface of the shell (gas path), and (3) the oil pool at the bottom of the shell (liquid path).

The importance of each transmission path to the shell was investigated by Holm³⁶ who found that the relative strength of each path depends on the compressor operating conditions. The gas path predominates when the compressor first starts

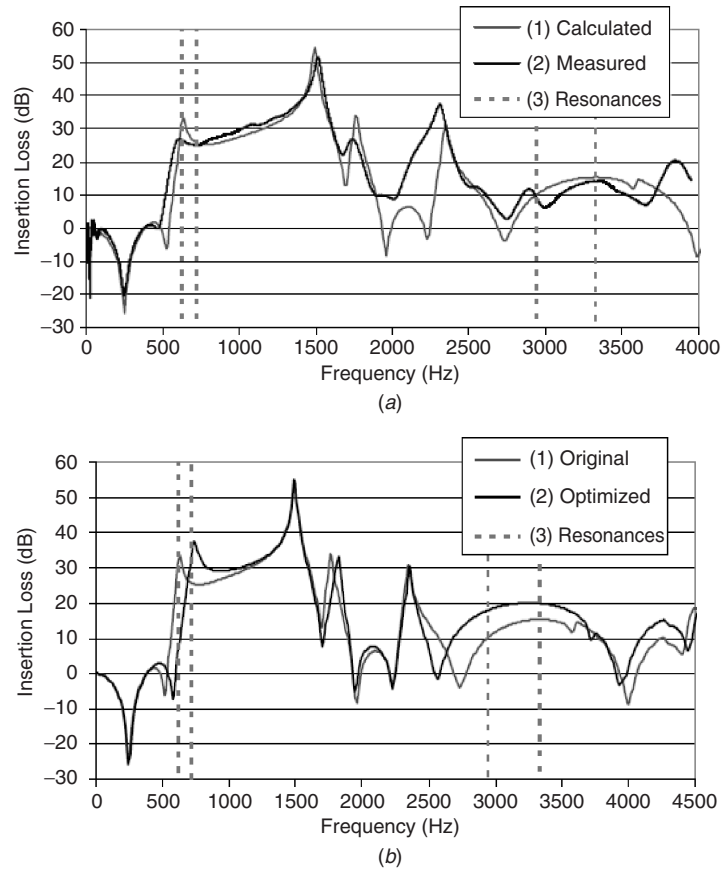

Figure 14 (a) Calculated and measured insertion loss of original muffler (1) calculated and (2) measured, together with (3) resonance frequencies.³³ (b) Calculated insertion loss of (1) original, (2) optimized muffler together with (3) resonance frequencies.³³

Figure 15 Measured sound power level of compressor at appliance operating conditions with (a) standard muffler and (b) optimized muffler. Averaged A-weighted spectrum of five compressors.³³

and the suction pressure is 200 kPa to 400 kPa higher than normal. When the initial pressure has reduced to the normal operating pressure, the gas path noise transmission reduces the compressor sound by approximately 15 dB. The noise transmission through the oil path is much less effective when it contains Freon or working fluid bubbles. When the oil contains bubbles, the noise transmission can be reduced by as much as 24 dB compared to the condition when it contains no bubbles. Special chemical additives that initiate bubble formation in the oil can be used to weaken the oil transmission path and reduce noise.

In one small refrigerator compressor, modal analysis tests, sound intensity contour plots, and sound power frequency spectra were measured in an attempt to identify sources and paths of vibration/noise energy transmission.³¹ Figure 17 shows that the sound power radiated was dominant in two one-third octave bands at 800 and 3150 Hz. Further investigation with excitation by a calibrated impact hammer and use of modal analysis software revealed that two modes of vibration at 2810 and 3080 Hz were responsible for the intense sound generated in the 3150-Hz one-third octave frequency band. The modal analysis contour plots and the mode shapes (see Fig. 18) show that for this compressor the intense sound in the 3150-Hz one-third octave band is radiated predominantly by the 2810- and 3080-Hz modes from the bottom of the compressor shell. The intense noise radiated in the 800-Hz one-third octave was found

to be related to forces fed through the compressor spring mounts to the shell resulting in shell sound radiation.³¹

Research has also been conducted on compressor shell vibration using theoretical models. Most small compressor shells have a cylindrical shape, of either circular or elliptical cross section with doomed end caps or plates at each end of the cylinder. The shell modes of vibration can be grouped into three main classes: (1) *cylindrical modes* in which large deflections of the cylindrical part of the shell occur, but the end plates remain essentially undeflected, (2) *top-bottom modes* in which large deflections of the end plates occur leaving the cylindrical part largely unaffected, and (3) *mixed modes* in which both the cylindrical and end plates undergo deflections simultaneously. Cossalter et al. studied the vibration response of a shell system to the main excitation forces (a) by the discharge pipe force and (b) by the spring suspension forces.²⁴ They showed that, with the elliptical cylinder shell studied, for the same force amplitude, the discharge pipe force excites more modes and with the seventh mode having a natural frequency of 2676 Hz with the greatest vibration amplitude.

To reduce shell vibration and noise, compressor shells very often are made much thicker than is

Figure 17 A-weighted sound power level frequency spectrum.³¹

Figure 18 Natural frequencies and the corresponding natural modes of the compressor shell.³¹

necessary for the mechanical strength requirements of the system. This means that high-capacity presses and more expensive progressive tooling are required, and the cost of the compressor is correspondingly increased. Using a different number of spring support systems, moving the location of the spring supports relative to the discharge pipe location, ensuring that the compressor shell natural frequencies are not close to any internal forcing frequencies, and increasing the shell damping can also all be effective in reducing the compressor shell radiated noise without the need to increase the shell thickness.

7.2 Noise Control of Rotary Compressors

As discussed before, there are many types of rotary compressors in use. Some noise control work has been conducted on such types.^{35,37–42} It is not possible to discuss the noise sources and methods of control on all of these types. Some case histories of noise control on rolling piston and scroll compressors are described here. Wang et al. have conducted noise control studies on a rotary compressor enclosed in a hermetic shell.⁴³

Figure 19 shows the compressor disassembled for modal testing. Figure 19c shows the complete compressor with one shell end cap removed. Figure 19a shows the shell with the rotor and cylinder only, while Fig. 19b shows the shell with the stator. Modal analysis and finite element analysis were carried out in parallel. The experiments were conducted first with the completely disassembled unit and then with the unit built-up step by step in order to understand the complicated dynamics of the complete compressor-shell structure. In this compressor, the stator and cylinder block are welded at three points to the shell. This makes the shell stiffer but allows vibrations of the cylinder assembly to be transmitted directly to the shell. It was found that the shell has its first structural natural frequency at about 600 Hz. Table 2 gives a comparison of the first five shell natural frequencies of the shell on its own calculated by (1) finite element (FE) analysis and (2) measured by the modal analysis tests.

When the rotor and cylinder block were attached, the natural frequencies of the shell were changed. The measured mode shapes and natural frequencies

Table 2 Comparison of Natural Frequencies of Compressor Shell Predicted by Finite Element (FE) Method with Those Measured

Mode number	1st	2nd	3rd	4th	5th
FE analysis (Hz)	616	1712	2465	2813	3153
Modal test (Hz)	635	1742	2464	2731	3132
Error (%)	3.0	1.8	0	2.9	0.7

Source: From Ref. 43.

agree qualitatively with those predicted. The measured natural frequencies are mostly within a bound of $\pm 3\%$ of the predicted values. The differences are presumably caused by inexact knowledge of the boundary conditions and imprecise geometrical descriptions used in the FE analysis. The attachment of the stator to the shell at the three interior shell weld points stiffens the shell and raises the natural frequencies considerably.⁴³

Wang et al. also studied the complete built-up compressor system using both FE analysis and modal testing.⁴³ The conclusion was that two main compressor resonances occurred. In the 1.5-kHz region, vibration of the cylinder block system excited the shell in a rigid body mode, while in the 3.5-kHz frequency region, the cylinder block vibration excited the shell in an elastic bending mode. Modal testing gave a frequency of 3368 Hz for the latter elastic mode, while FE modeling predicted a frequency of 3512 Hz for this mode. It was concluded that, for the elastic bending mode in the 3500-Hz region, the nodal points were close to the weld points. It was thought that most of the vibration energy was transferred to the shell from the cylinder assembly at these weld locations. The rotation of the rotor is supported by the motor and pump bearings and it was believed that these are the main sources of excitation for the shell vibration in the 3500-Hz frequency region. To reduce the excitation, the hub length of the motor bearing was increased to try to make the shaft rotation more stable.⁴³ See the extended part shown in Fig. 20.

The bearing modification reduced the compressor noise not only in the 3500-Hz frequency range but in

Figure 19 Modal test models: (a) shell with rotor and cylinder, (b) shell with stator, and (c) full model.⁴³

Figure 20 Schematic diagram of rotor and cylinder block and modification of the rotor bearing.⁴³

the 1500-Hz range as well. See Fig. 21. Note that the sound pressure level results in Fig. 21 have been A-weighted to give an approximate idea of the loudness of different frequency regions of the noise.

7.2.1 Rolling Piston Compressors In a rolling piston compressor, the interaction between the suction and discharge pressure pulsations, mechanical forces, reciprocating motion of the sliding vane, roller motion, roller driving forces, and electromagnetic forces in the electric motor is very complicated. Refrigerant gas pulsations take place on both the low- and high-pressure sides of the rolling piston system. During the compressor operation, the rolling piston and sliding vane divide the gas into variable volume suction chamber and discharge gas chamber volumes. (See Fig. 8.) The suction chamber is asymmetric in shape and during operation, flow reversal occurs resulting in intense pressure fluctuations and turbulence, although the suction pressure fluctuations are reduced to some extent by the external accumulator. The suction port acts somewhat as a throttle. In addition, the discharge gas pulsations can excite the different cavity volumes inside the shell and also the fluctuating magnetic field and the resulting fluctuating electric motor torque result in forces transmitted to the hermetic compressor shell. It is difficult to model the forced vibration and noise system as a whole. Experimental approaches to reduce vibration and noise radiation are normally used.

In one study, the vibration magnitudes were mapped over the shell surface.⁴⁴ High levels of vibration at different frequencies were recorded on the

shell above and below the electric motor stator, on the accumulator strap, and near to the wire welds and suction line. Three main methods of reducing the compressor vibration and noise were applied successfully: (1) a vibration damper consisting of wire loops wound around the compressor housing near to the regions of maximum vibration magnitude resulted in an A-weighted sound pressure level reduction of 2.5 dB, (2) modification of the suction inlet passageway to provide a smoother inlet passage, a narrow smaller cross-section passage to act as a diffuser throat and a more symmetric inlet passage in the cylinder sidewall to connect with the cylinder suction volume produced a drop in the A-weighted sound pressure level radiated of about 2.0 dB, and (3) a redesigned rotor and crankshaft thrust bearing made of low-friction polyamide material gave a further A-weighted sound pressure level reduction of about 2.0 dB. See Fig. 22.

Larger household refrigerators continue to be in demand by consumers. Such refrigerators require larger compressors that tend to be more noisy. Although a single rotor rolling piston rotary compressor can be produced to have more cooling capacity and be more efficient than an equivalent reciprocating compressor, it can suffer more from vibration and noise problems. To reduce vibration and noise a twin-rotor rolling piston compressor was developed. This compressor is about twice as big and has twice the weight of a single-rotor rolling piston compressor, and it has twice the cooling capacity. This twin rotor compressor has about one-third of the compression torque and only about one-fifth of the vibration amplitude of an equivalent cooling capacity single-rotor compressor.³⁹

Figure 23 compares the spectra of the sound pressure levels produced by single- and twin-mechanism rolling piston rotary compressors.³⁹ It is observed that for the larger 480-liter capacity refrigerator, the twin-rotor design is about 7 dB quieter than the same capacity single-rotor design. The lower noise is particularly evident at high frequency above about 1000 Hz.

7.2.2 Scroll Compressors The noise characteristics of a scroll compressor vary considerably with load. Measurements must be conducted under real load conditions to investigate the operating noise characteristics of the compressor. It is difficult to carry out noise source identification under load conditions.

Figure 21 A-weighted sound pressure levels before and after modifications to the compressor.⁴³

Figure 22 Effect of the use of the modified thrust bearing on the compressor noise.⁴⁴

Figure 24 shows a typical test setup for noise identification studies on a high-pressure scroll compressor by Zhao et al.⁴⁵

In another study by Kim and Lee, identification of noise sources on a scroll compressor and redesign of its structure were performed.⁴² An array of 15 microphones was used to identify the noise sources on the

Key

- o Twin-mechanism rotary compressor for 480-liter refrigerator
- Single-mechanism rotary compressor for 350-liter refrigerator

Figure 23 Compressor noise. The sound pressure level was measured at 30 cm from the compressor shell with the compressor operating on a 50-Hz supply.³⁹

compressor. Since the noise generated depends considerably on the load, the noise source identification was conducted under load. It was found that the noise was predominant in the 1600-Hz and 2500-Hz one-third octave frequency bands. Structural resonances of the upper frame and fixed scroll were found to be at

Figure 24 Test system for tests on a scroll compressor.⁴⁵

1458-Hz and 1478-Hz, respectively. It was observed from holograph measurements that the 1600-Hz one-third octave band noise is related to impacts between the fixed scroll and the upper frame, while the noise in the 2500-Hz one-third octave band is related to the sound radiated from the upper chamber.⁴²

For the reduction of the impact noise, damping material that had good characteristics at high operating temperatures was used. The thickness of the material chosen was 1 mm, as shown in Fig. 25. The material was applied to the upper frame. As a result, the A-weighted sound pressure level was reduced from 68.1 dB, when the original fixed scroll was used, to 56.2 dB when the modified fixed scroll was used, as seen in Fig. 26. By inserting a 0.5-mm-thick copper sheet between the interchamber and the upper frame, the transmission of impact energy was reduced and this resulted in a further 3.3-dB reduction.

As a result, an A-weighted sound pressure level reduction of about 12 dB was achieved by the use of damping material. Further modifications of the upper chamber and the fixed scroll were not put into practice because of manufacturing difficulties. The sound pressure level of this compressor was higher than usual because of the use of a compressor type in which the internal components can be changed easily. The overall noise level reduction achieved by the use of the damping material on its own was about 12 dB.

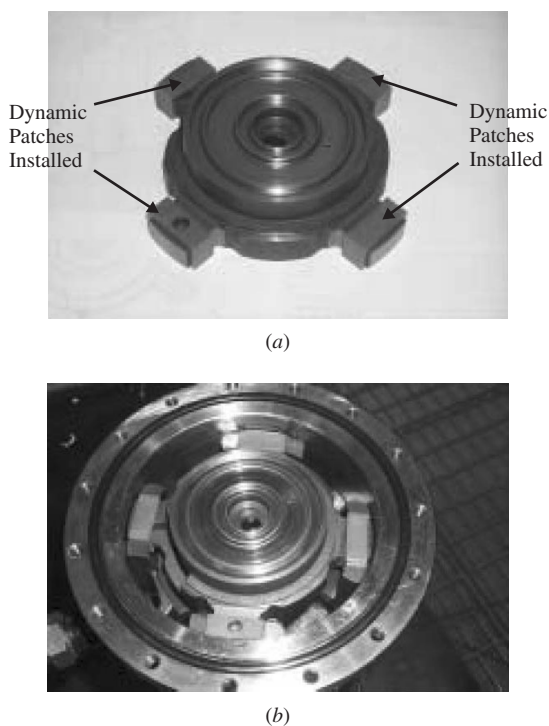

Figure 25 Damping material used for impact noise reduction on a scroll compressor.⁴²

Figure 26 Comparison of A-weighted sound pressure level before and after treatment.⁴²

8 CASE HISTORIES OF THE NOISE CONTROL OF DYNAMIC COMPRESSORS

8.1 Noise Control of Centrifugal Compressors^{43,46-48}

Jeon and Lee⁴⁸ have studied the possibility of reducing the noise of a high-speed centrifugal compressor designed to operate nominally at 14,500 rpm in a turbochiller. This type of compressor-chiller unit is typical of those used to cool large buildings. The chiller uses R134a as the refrigerant. See Fig. 27a. The rotational speed (rps) in cycles/second (Hz) is thus $14,500/60$ or about 258 Hz. The impeller has 11 long blades and 11 short splitter blades, making a total of 22 blades (see Fig 27b). The inlet guide vane has 7 blades and the diffuser has 13 blades. The main noise sources were found to be related to the blade passing frequency (BPF) of the impeller and to the aerodynamic interaction of the impeller and the diffuser and impeller and inlet guide vane (IGV). The dominant noise occurs at the 22 BPF of the impeller, nominally at $14,500 \times 22/60$, or about 5317 Hz. See Fig. 28. Sound is also generated at frequencies of $\text{rps} \times 11$, $\text{rps} \times 22$, $\text{rps} \times 33$, and $\text{rps} \times 44$. With such centrifugal compressors, the high-frequency sound is normally generated at the elbow and radiated from the duct there. The low-frequency sound generated propagates into the duct, excites the condenser wall, and is reradiated as noise by the wall. In this case history, both sound-absorbing material and a redesigned elbow were used to reduce the noise.

The rotating impeller is normally the main source of noise in such compressors. The noise is also caused by interactions between the impeller and the inlet guide vanes and between the impeller and the diffuser. The identification and location of the main noise sources on this compressor were investigated by the use of sound intensity using an intensity probe and by vibration measurements using an accelerometer. The sound pressure levels were measured near to the condenser and near to the evaporator. The sound

Figure 27 (a) Turbochiller unit and (b) impeller used in the compressor. ⁴⁸

Figure 28 Measured acoustic signal of centrifugal chiller.

pressure level was found to be 10 dB higher near the condenser than near the evaporator. The sound pressure level was then measured at 1.5 m from the side of the condenser.

Figure 28 shows the measured spectrum of the sound pressure level at 1.5 m from the condenser. It is seen that the spectrum is dominated by the BPF peak at 22 times the rps, or about 5360 Hz. This frequency is shown in Fig. 28 as 22x (5360). The second harmonic of the BPF is also quite strong and is indicated in Fig. 28 by 44x. The other PBF caused just by the 11 compressor blades is shown as 11x together with its third harmonic shown as 33x. The interaction peaks of the impeller-guide vane and the impeller-diffuser are shown in Fig. 28 as 4x (Im-IGV) and 9x(Im-diff), respectively. Figure 29 shows spectra of the acceleration magnitude measured on the volute, elbow duct, and condenser wall.

It is seen that the acceleration is the highest on the elbow duct, while that on the volute is the lowest.

The acceleration magnitude on the condenser wall is intermediate. The levels are particularly high at the BPF of about 5360 Hz and the second harmonic at about 10,720 Hz. The accelerations measured on the elbow duct, condenser wall, and volute at the BPF were 83.2, 19.9, and 14.9 m/s². Assuming that the radiation frequencies are similar for the three components and remembering that the sound power radiated is related to surface space-averaged velocity squared, the elbow duct can be assumed to be a very strong noise-radiating surface.

To test these assumptions, the turbochiller was completely lagged in sound-absorbing material and a drop of about 9 dB overall was observed. See Fig. 30. The drop in sound pressure level at the BPF was 11.7 dB. Then to attempt to determine the importance of the noise radiated by the elbow duct, the sound-absorbing material was removed from this area. The overall level was increased from 83 to 87 dB, although

Figure 29 Measured acceleration.

Figure 30 Effect of sound-absorbing material.⁸

it should be noted that the elbow duct area is relatively small.

When the sound-absorbing lagging was removed from the condenser wall, but not from the elbow duct, the overall sound pressure level was also increased from 83 to 87 dB, despite the fact that the area of the condenser walls is about 50 times that of the elbow duct. Several analytical studies have been also performed to try to predict compressor noise radiation from centrifugal compressors.⁷

9 NOISE CONTROL IN COMPRESSOR INSTALLATIONS

Mobile compressors are used on building sites, highway construction, and for other similar purposes. They are normally enclosed to reduce noise, but interior heat rejection and buildup requires the use of a cooling fan, which causes additional noise problems. Chapter 54 includes a case history on mobile compressor noise reduction.

The control of the noise of large industrial compressors poses a different problem from that of mobile compressors and small household compressors, which are mainly of the positive displacement design. Since there are very many different compressor designs of various capacities and uses, each noise problem in most cases is unique to the particular application. In many cases, noise control of the compressor must be accomplished during or after its installation in service. In such cases, well-established passive noise control approaches are used. Such approaches are discussed in Chapter 54. These approaches are also described well in several books.

Slow-speed industrial reciprocating compressors are generally much quieter than other large industrial types. The A-weighted sound pressure level at 1 m is usually in the range of 85 to 95 dB. Since manufacturers' data are often difficult to obtain, in many cases, it may be necessary to make noise measurements near to the compressor in question before trying to apply passive noise and vibration control approaches. The passive noise control measures usually applied to compressors include the use of (1) enclosures, (2) sound-absorbing materials, (3) mufflers/silencers applied upstream and downstream, (4) vibration isolation, and (5) barriers. See Chapter 54.

If the compressor is driven by an electric motor or internal combustion engine motor, then the motor may produce more noise than the compressor itself. In such a case it is often necessary to enclose both the compressor and the motor. As a compressor becomes larger, its surface area increases more slowly than its volume, and natural heat rejection from its surface area is normally insufficient. The related enclosure interior heat buildup increases, and so use of a forced-draft system to ensure adequate cooling is essential. If both the compressor and its power source (motor) are enclosed, it is normal to enclose each separately and to ensure that a greater positive pressure is maintained in the motor enclosure than in the compressor enclosure. This positive pressure difference is important if gases other than air are being compressed and prevents the possibility of gases reaching the motor that could cause corrosion, or in the case of combustible gases, even an explosion.

Most such large industrial compressors have much greater flow rates than smaller household types and in the case of large dynamic centrifugal and axial compressors, they have much higher flow velocities as well. In the case of large reciprocating compressors, pressure pulsations that occur in the compression chambers result in sound waves transmitted into inlet and exhaust compressor ductwork. It is common practice to incorporate either absorbent or reactive silencers/mufflers upstream and downstream of the compressor to reduce inlet and exhaust noise.

10 CONCLUDING DISCUSSION

Work on reducing the noise and vibration continues. Papers may be found in several different journals and conference proceedings. It is impossible to review

all of these in detail in this short chapter. The proceedings of the International Compressor Engineering Conferences held biannually at Purdue University are a good source of papers on recent work on compressor noise and vibration.^{49–80} For instance, in the 2004 and 2006 proceedings papers can be found on the noise of reciprocating compressors,^{49–51,60,61} the noise of rotary compressors and the increasingly popular scroll compressor,^{52–57} muffler design,^{58–61} sound quality,^{62,63} compressor vibration,^{64–70} and a variety of other compressor noise and vibration research topics.^{71–80}

CHAPTER 75

VALVE-INDUCED NOISE: ITS CAUSE AND ABATEMENT

Hans D. Baumann
Palm Beach, Florida

Mats Åbom
The Marcus Wallenberg Laboratory for Sound and Vibration Research
KTH—The Royal Institute of Technology
Stockholm, Sweden

1 INTRODUCTION

On-off valves operating generally at low fluid velocities usually pose no noise problems. However, control valves that are widely employed in industrial applications and that are used to reduce pressure can be the source of significant sound pressure levels, exceeding in some cases 130 dB at the exterior of a steel pipe. One has to distinguish among different noise-producing mechanisms to take corrective measures, if needed. These are, in order of importance: aerodynamic noise caused by high gas velocities; cavitating, and to a lesser extent, turbulent liquid flow; noise caused by resonant vibration of valve components; and, finally, “whistling” sound caused by resonant coupling of sound waves with gas flow.

While unwanted noise is a source of annoyance, it can also have legal and safety consequences. For example, the Occupational Safety and Health Administration (OSHA) regulations limit the 8-h A-weighted sound pressure level exposure for workers to 90 dB. On the other hand, a continuous A-weighted sound pressure level exposure at 1 m from an uninsulated pipe of about 130 dB can cause structural pipe failures¹ and therefore can have dire consequences. It is for all of these reasons that the use of a reliable and reasonable noise prediction method is a must in the evaluation of proposed valve purchases to avoid problems after installation.

2 FUNDAMENTAL CONSIDERATIONS

All control valves basically control the rate of flow and through this mechanism the downstream pressure, temperature, or liquid level in a tank, to name a few. In order to do so, a valve must have a higher inlet pressure than the downstream pressure. This *potential energy* is then converted first into an acceleration of the fluid or into *kinetic energy* and finally through turbulence or shock waves in heat, or *thermal energy*. This kinetic energy can produce sound power (W_a) as a byproduct.

The amount of sound power is typically a small fraction of the *mechanical power*, W_m , that is converted into heat:

$$W_m = mU^2/2 \quad (\text{W}) \quad (1)$$

where m = mass flow (kg/s), and U = jet velocity (m/s). The acoustic power is given now by the mechanical power multiplied by an *acoustical efficiency factor*, η , making

$$W_a = \eta W_m \quad (\text{W}) \quad (2)$$

This equation works both for noise produced by liquid turbulence as well as for aerodynamically produced noise. The acoustical efficiency factor for turbulent liquids² is given by $(U/c_l) \times 10^{-4}$, while η for aerodynamic noise³ at sonic velocity (Mach 1) is also given by $(U/c_g) \times 10^{-4}$, where c_l is the speed of sound in liquids and c_g is the speed of sound in gases in metres per second.

In some valve types only a fraction of the internally generated sound power escapes into the downstream pipe. An r_w coefficient³ describes this fraction. For globe valves r_w is assumed to be 0.25. While the resultant numbers seem small, in practice pipe internal sound power nevertheless can reach magnitudes of more than 10 kW. Fortunately for us, most valves are installed in a piping system where most of the sound power is reflected by the pipe wall. The difference in sound pressure level between the interior and the exterior of the pipe is called the transmission loss (TL). Typical values of transmission losses range between 40 and 60 dB.

Finally, there is a decrease in the observed sound pressure level between the pipe exterior and the distance to the observer (typically 1 m). Here the distance correction is equivalent to $10 \log_{10}[(h + D_0/2)/D_0/2]$, where h is the distance between pipe wall and observer and D_0 is the outside diameter of the pipe.

3 AERODYNAMICALLY PRODUCED SOUND

This is the most common type of acoustic annoyance in industrial plants. Fortunately, reliable prediction techniques are now available through the International Electrical Commission (IEC) Standard 60534-8-3. This standard³ is based on the original work by Lighthill⁴ covering free jet noise and further modified by Baumann⁵ to account for the behavior of confined jets, the effects of pressure recovery, and

Table 1 Typical F_d Values of Control Valves. Full Size Trim

Valve Types	Flow Direction	Max. C_1/d^2	F_N	F_d @% of Rated Flow Capacity (C_1)					
				10	20	40	60	80	100
Globe, parabolic plug	To open	13	0.28	0.10	0.15	0.25	0.31	0.39	0.46
Globe, 3 V-port plug	To open	10	0.44	0.29	0.40	0.42	0.43	0.45	0.48
Globe, 4 V-port cage	Either ^a	10	0.38	0.25	0.35	0.36	0.37	0.39	0.41
Globe, 6 V-port cage	Either ^a	10	0.26	0.17	0.23	0.24	0.26	0.28	0.30
Globe, 60-hole drilled cage	Either ^a	8	0.14	0.40	0.29	0.20	0.17	0.14	0.13
Globe, 120-hole drilled cage	Either ^a	6.5	0.09	0.29	0.20	0.14	0.12	0.10	0.09
Butterfly, swing-through, to 70°	Either	32	0.34	0.26	0.34	0.42	0.50	0.53	0.57
Butterfly, fluted vane, to 70°	Either	26	0.13	0.08	0.10	0.15	0.20	0.24	0.30
Eccentric rotary plug valve	Either	13	0.26	0.12	0.18	0.22	0.30	0.36	0.42
Segmented V-ball valve	Either	21	0.67	0.60	0.65	0.70	0.75	0.78	0.80

^a Limited $P_1 - P_2$ in flow toward center, d = valve size in inches, and F_N = valve-specific noise parameter, defined by the author as the F_d at a flow capacity (C_v) equivalent to $6.5d^2$. Depending upon pipe size, a lower F_N means less external noise due to higher pipe wall attenuation. Courtesy ISA.

the influence of jet diameter on the peak frequency, which in turn determines the magnitude of the transmission loss. This method has been improved (the last revision dates from the year 2000) and gives prediction accuracies for the A-weighted sound pressure level typically within a range of ± 3 dB. This assumes, of course, that all service conditions are known and that valve type specific sizing parameters such F_L and F_d (see Table 1) are known. The F_L factor is used to calculate the exact gas or liquid velocity in the restricted jet diameter portion of the valve. This velocity in turn then determines the amount of mechanical power that is converted into heat, and, second, the type of noise-producing mechanism for gases such as dipole (predominant when the jet interacts with wall surfaces of the valve) or quadrupole (free jet turbulence). The IEC method assumes from Baumann⁶ that both dipole and quadrupole sources are of equal magnitude at a jet velocity of Mach 1. Here the acoustical efficiency η is assumed to decrease from 10^{-4} at a rate proportional to $U^{3.6}$. Shock cells predominate at supersonic velocities, which can exist downstream of the valve's orifice; here the acoustical efficiency increases proportional to $M^{6.6}$ to finally reach a maximum⁷ at 1×10^{-3} at a Mach number of 1.4. The F_d factor is equally important since it determines the size of the jet emanating from one or more valve orifices. This in turn defines the peak frequency f_p (Hz) of the sound pressure level inside the pipe, where

$$f_p = 0.2 \times U / (F_d d) \quad (3)$$

where d = the apparent orifice diameter (in metres) as calculated from the total flow area. For low noise valve trims consisting of cages with multiple drilled holes (see Fig. 6), $F_d = 1/N_0^{0.5}$, where N_0 defines the number of equally sized holes. For example, a trim having 100 identical passages in parallel for the fluid to pass through has an F_d of 0.1. As a general rule,

valves having a high F_L number but a low F_d factor are less noisy (see Table 1).

The reader may sense that modern noise prediction techniques are quite complex and really require a programmed computer. It is for this reason that we do not want to reproduce the whole prediction schema but like to offer instead a simplified graphical method (courtesy of The International Society of Measurement and Control, ISA) as shown in Fig. 1. While not as accurate as a computerized method, this graph nevertheless will give an idea whether a given valve will likely exceed a given noise limit.

Here is how to use this method: First, find the P_1/P_2 ratio, that is, the absolute inlet pressure divided by the absolute outlet pressure. Next read up to the given valve size and obtain the corresponding "basic sound pressure level" A from the scale on the left. The next step is to correct for the actual inlet pressure. This is given by $B = 12 \log(P_1/667)$ where the pressure is in kilopascals. Finally, add C , a correction for the pipe wall if it is other than Schedule 40. Here $C = +1.4$ for Schedule 20, 0 for Schedule 40, -3.5 for Schedule 80, and -7 for Schedule 160. The total sound level now is the sum of $A + B + C$. Subtract another 3 dB in case of steam.

Example An 80-mm (3-in.) globe valve with parabolic plug is reducing steam pressure from 3600 to 2118 kPa; the pipe Schedule is 80. Going to Fig. 1, we do not find a 3-in. valve. However, we can extrapolate between the lines and find the A factor to be 98 dB for the pressure ratio of 1.7. Factor B calculates as $12 \log(3600/667) = 8.8$ dB. Finally we add -3.5 dB for Schedule 80 and we subtract 3 dB for steam. This results in a total A-weighted sound pressure level of 100.8 dB at 1 m from the pipe wall. Using the computerized IEC equations gives an A-weighted sound pressure level of 103 dB.

4 HYDRODYNAMIC SOUND

For cases with a "incompressible" medium (liquids) the Mach number is normally very small, and it can

Figure 1 Basic aerodynamic A-weighted sound pressure level in decibels for conventional control valves at approximately 70% of rated flow capacity, at 667-kPa inlet pressure and schedule 40 downstream pipe, measured 1 m from the downstream pipe wall. (Courtesy ISA.)

Figure 2 Principal behavior of cavitation in a valve, P_1 and P_2 denote upstream and downstream static pressure, respectively. When the minimum static pressure is less than a certain critical value (P_{2r}) cavitation starts. When the downstream pressure P_2 is less than the vapor pressure P_v , a phenomenon called “flashing” can occur. In this case a liquid-gas mixture approaches the vena contracta and partial vaporization of the liquid occurs during acceleration of the flow.

be expected that the monopole type of mechanism will dominate.² In liquids there is also the possibility

for cavitation, that is, the creation of vapor-filled bubbles that then implode. The rapid collapse of the bubbles can create very high local pressure peaks with levels up to 10^{10} Pa that can result in mechanical damage.⁸ When the flow is accelerated toward the vena contracta of a valve, the speed increases and the static pressure drops, in accordance with Bernoulli's equation; see Fig. 2. Cavitation starts when the local static downstream pressure reaches a certain critical limit P_{2r} , the value of which depends on the temperature and the amount of solved gas in the liquid. The minimum value for the critical pressure is the vapor pressure of the liquid P_v . The IEC Standard 60543-8-4⁹ introduces an incipient cavitation pressure ratio $(P_1 - P_2)/P_1$ at which cavitation commences; it is called X_{fz} . Typical values for X_{fz} are given by the valve manufacturer. Values range from 0.2 for large valves to 0.35 for small valves.

The principal behavior of cavitation noise¹⁰ can be illustrated by Fig. 3. At $(P_1 - P_2)/P_1 < X_{fz}$ the emitted sound increases due to a process of fluid-induced turbulence. Above this pressure ratio cavitation commences quite rapidly and then reaches a maximum. The sound pressure level thereafter decreases again as more vapor is produced and then reaches a point that corresponds to the continuing slope of the turbulent noise. At this stage we have “flashing,” that is, the vapor bubbles no longer collapse. One should also realize that valves operating in the laminar flow regime do not experience

Figure 3 Test data taken for 25-mm globe valve with a parabolic plug, flow to open. Calculated values are represented by solid line. The flow coefficient and other data are: Valve sizing coefficient $2.16 \times 10^{-4} \text{ m}^2$ ($C_v = 9 \text{ gal/min (lb/in}^2\text{)}^{0.5}$). Jet diameter = 0.0285 m, $F_L = 0.9$, $F_d = 0.38$, $X_{fz} = 0.32$. $P_1 = 1000 \text{ kPa}$.

Figure 4 Use of multistage arrangement to create a certain pressure drop without reaching the critical cavitation pressure in the system, see also Fig. 5.

cavitation. A good way to avoid cavitation in large valves is to use a special valve trim having multiple throttling stages as shown in Figs. 4 and 5.

Prediction of cavitation noise is even more complex than that of aerodynamic noise, and the reader is referred to IEC Standard 60543-8-4 or to Ref. 9. One should note that, in contrast to aerodynamic noise, for water the point of maximum sound transmission through the pipe wall is at the ring frequency of the pipe (f_r), where, for steel pipes $f_r = 5000/3.14D_i$ (Hz) and D_i = the inside diameter of the pipe (m).

5 MECHANICAL NOISE

This normally originates from the valve plug and is mainly a problem in liquid-filled systems and especially if there is a gas–fluid mixture involved. The cause is periodic flow separation creating fluctuating fluid forces, which excite structural vibrations in the valve plug + stem, for example, bending modes. A particularly dangerous situation arises when a periodic flow phenomenon around the valve plug, characterized by a Strouhal frequency f_{St} , is close to a structural eigenfrequency f_{Mek} , where $f_{Mek} = 0.16 \times (\text{spring rate of the valve stem/mass of valve plug})^{0.5}$. This can create a self-sustained oscillator, which means that the two phenomena form a positive feedback loop, where energy from the mean flow is fed into the structural eigenfrequency. A growing oscillation at a dominating frequency will then be created, limited in amplitude only by losses or nonlinear effects.^{11,12} This type of phenomenon is normally referred to as valve screech and can create very high vibration amplitudes with risk for mechanical failure as well as high emitted noise levels. Screech can also be created by interaction between an acoustical mode in the pipe system and a structural valve mode. Also for this case, the energy feeding the structural and acoustical modes is taken from the mean flow via the fluid forces acting on the valve plug. To eliminate valve screech, there exist two main alternatives: (i) to disturb or reduce the amplitude of the periodic flow phenomenon at the valve plug (sometimes a reversal in flow direction will help) and (ii) to damp or move the mechanical eigenfrequency (reduce the weight of the plug, or, increase the stem stiffness

Figure 5 Single-flow area, multistep valve plug. This low-noise trim uses 11 throttling steps with a single, annular flow area. Note, areas gradually enlarge to accommodate changes in gas density due to lowering of pressure. Benefits are lower throttling velocities.

by shortening its length or increasing its diameter). Concerning the first alternative, typical methods are based on decreasing the pressure drop across the valve or using geometrical modifications to reduce flow instabilities.

6 WHISTLING

Another powerful sound source also related to the creation of a self-sustained oscillator is whistling.^{11,12} This can occur when a periodic flow phenomenon forms a positive feedback loop with an acoustic eigenfrequency. Two possibilities exist, either at a low-frequency plane wave mode, corresponding to a multiple of half a wave length in a pipe branch, or the cutoff frequency for a higher order mode over a pipe cross section.^{12,13} The first case normally corresponds

to low-frequency tones (up to a few hundred hertz) while the nonaxial case typically correspond to the kilohertz range.¹³ Presently, there are no simple methods to predict with certainty the existence or the level of fluid-driven self-sustained oscillators. Fortunately, this is a rather rare phenomenon.

7 MEASUREMENT OF VALVE NOISE

For gas-filled systems most of the generated sound will be emitted on the downstream side of the valve.⁷ For liquid-filled systems there is typically a more uniform distribution and the sound tends to radiate equally in all directions, that is, around 50% of the power is radiated from the valve body and 25% is radiated up- and downstream.² Normally, valve noise measurements are based on the international standard¹⁴ IEC 60534-8-1. Testing is done by placing the valve into an anechoic chamber to isolate the valve from ambient noises. Negligible downstream reflections are required; so a reflection-free termination must be used. Basic measurements consist of measuring the A-weighted sound pressure level 1 m downstream from the valve outlet and 1 m perpendicular from the pipe wall. Radiated sound power can be calculated by taking into account the transmission loss of the pipe wall.

8 ANALYSIS OF PIPE SYSTEMS

The standard approach for an acoustic analysis of a complete pipe system is to use power-based methods, that is, each source is treated separately, and the resulting acoustic power from several sources is simply obtained by addition. The sound power in a pipe is assumed to propagate along the system where it is attenuated by natural damping at the walls and radiation or by dissipative silencers. This power-based approach is valid for broadband sources and for frequencies well above the plane wave range. A useful guideline for an acoustic power-based analysis of noise in pipes is the VDI 3733.¹⁵ For the plane wave range strong standing-wave effects and coupling between acoustic sources can be expected, which will change the acoustic power output. For this low-frequency range, power-based methods should not be used; instead more detailed analysis methods based on acoustic two-ports is more appropriate; see Chapter 85 in this handbook.

In the power-based methods the effect of multiple reflections is normally neglected. Such reflections can lead to an increase in the sound power level inside a pipe and thereby to an increase in the radiated level and are therefore important to include. A recent treatment of the problem that offers a new formalism based on two-ports for acoustic power flow, is the work of Åbom and Gijrath.¹⁶ The new formalism has the advantage of having the same structure as the existing two-port formalism for the plane wave range. This means that existing codes for two-port plane wave analysis easily can be modified and used for a power-based analysis that takes multiple reflections into account.

9 NOISE REDUCTION METHODS

Noise reduction measures can either be applied at the valve itself or along the transmission path; both of these alternatives will be discussed below.

9.1 Reduction at the Valve

Here the discussion will focus on the steady-state noise associated with control valves. From a thermodynamic point of view a control valve converts pressure energy into heat to control the mass flow. The heat conversion normally takes place via turbulent flow losses with associated noise generation. Of course, it is possible to design control valves where the heat production is created via laminar flow losses, but that is quite impractical. Standard valve designs are based on turbulent dissipation and for such valves the generated noise is proportional to orifice velocity to the 3.6th power.⁶

The first alternative is to use so-called single-flow path, multistage valve trims where a desired pressure drop is split into a number of steps. Assuming an unchanged jet area and N equal steps that act as independent sources, the individual pressure drop per stage and its corresponding velocity is lower, producing less total sound power ($\sim N^{2.6}$) compared to the single-step arrangement.

For instance, with three steps the reduction in sound power will be around 12 dB. Unfortunately, for gases, the area of each stage has to be expanded to accommodate the density changes. This then negates a good part of the above noise reduction. An example of a multistage pressure reduction trim is shown in Fig. 5.

Noise reduction for a given valve can also be achieved by a series of carefully designed downstream throttling plates as described for instance by Hynes.¹⁷ Here the pressure drop across an inherently noisy valve is reduced by up to 90% and instead shifted to the multistep and (high-frequency producing) multihole plates. As a result, an overall A-weighted noise level reduction of up to 25 dB can be achieved.

The second alternative is the so-called single-stage multiple-flow path valve trims, where the outlet jet is split into a number of smaller jets. This procedure will lead to a substantial increase in the peak frequency (f_p), which in turn increases the pipe's transmission loss. Here $f_p = 0.2U/d_H$ (Hz), where d_H is the hydraulic diameter (m) of the jet (or each of multiple jets).³

For high frequencies in the mass-damped region of the pipe, the increase in transmission loss is proportional to 6 dB per octave. Thus, reducing the size of an orifice by a factor of 10 (hence increasing the peak frequency by 10) can reduce the external A-weighted sound pressure level by 20 dB. No wonder that this is by far the most popular method of reducing valve noise; see Fig. 6. Care should be taken not to place adjoining orifices too close to each other in order to avoid jet

interaction. This will create combined larger jet diameters and therefore negate the desired peak frequency increase.

It is also possible to combine both alternatives and design multipath and multistage valve trims as shown in Fig. 7. Some of these trims operate at peak frequencies of up to 50 kHz. The question then is why is there any concern for noise, since the human ear cannot hear above 20 kHz?

Well, the reason is the sound pressure level inside the pipe decreases from the peak frequency level at a rate of about 6 dB per octave ($20 \log f$). Thus, there is still a substantial amount of sound escaping at the point of the lowest transmission loss (the first coincidence or cut-on frequency f_{c1} for gases^{3,6}). For example, let's assume $f_{c1} = 8000$ Hz and $f_p = 50,000$ Hz. The sound pressure level at the peak frequency is assumed to be 146 dB. The pipe internal sound pressure level at f_{c1} will now be $146 - 20 \log (f_p/f_{c1}) = 130$ dB. Assuming a pipe transmission loss of 46 dB gives an external sound pressure of $130 - 46 = 84$ dB outside of the pipe wall. If this valve would have had a standard trim operating at a peak frequency close to f_{c1} , the external sound level would have been $146 - 46 = 100$ dB.

A more modern low-noise trim is shown in Fig. 8. Here we have multiple inlet orifices separated by a resonant settling chamber and then followed by additional multiple outlet ports (total outlet area adjusted for lower downstream density). The inlet ports are well rounded and have the general shape of a venturi, thus deliberately creating supersonic jets with lower, or terminal, acoustic efficiency due to shock-cell interaction. Here more than 90% of the pressure energy is converted within the inlet orifice alone. The last, multiple exit stages are on purpose not streamlined and therefore operate at relatively low velocity (below Mach 1) and essentially at the less efficient quadrupole mechanism. This is believed to be the first low-noise valve trim taking advantage of the latest acoustic theories. Thus, it offers noise reductions of about 30 dB over conventional trims while being very compact.

10 VALVE NOISE REDUCTION GUIDELINES

Here are some guidelines on how to handle anticipated noise problems with valves. These are applicable for both liquids and gases. The listing is in order of severity.

Source Treatment

- Specify a valve trim that has a low-pressure recovery (high F_L factor); this will reduce jet velocity. Typical noise savings 5 dB.*

*A single-stage cage or plug is limited to a pressure ratio (P_1/P_2) of about 4:1 unless a multistage trim (nested cage) is used.

Figure 6 Multiorifice cage trim. Single-step but multiple flow passages characterize this cage trim. Benefits are higher internal peak sound frequencies and resultant increase in pipe transmission losses. Hence lower external noise.

- Use a multistep trim. Typical noise reduction 10 dB.
- Specify a multiported cage or valve plug.¹¹ Noise reduction about 15 dB.
- Consider a combined multiported and multistep trim* Noise savings typically 25 dB.
- Combination of low-noise trim and multiported plate (or plates) installed in downstream pipe. Noise reduction up to 30 dB.

Path Treatment

- Acoustic (or thermal) lagging[†] Reduces noise typically by 20 dB.
- Silencer downstream (gas only). Noise reduction up to 15 dB.
- Silencer upstream and downstream (gas only). Noise reduction typically 30 dB.

*Check for gas velocity in the valve outlet port if P_1/P_2 ratio is high. Outlet velocity should not exceed 0.2 Mach.

[†]It is preferable to reduce at least a portion of the generated sound pressure level within the source. Remember, source (valve) sound pressure levels above 110 dB can lead to mechanical failures due to associated high vibration levels.

Figure 7 Labyrinth-type cage insert featuring a combination of multistep and multipath grooved flow channels for reduced velocity and increased frequency benefits.

Figure 8 Two-stage, multipath, low-noise trim fabricated from identical stampings. Inlet passages are streamlined to create supersonic jets under high-pressure ratios while outlet areas have more abrupt passages with increased cross sections for subsonic velocities. Both passage sets are separated by a settling chamber. (Courtesy Fisher Controls International.)

Figure 9 Reduction in sound pressure level caused by acoustical lagging based on Eq. (6) using a 0.5-mm steel sheet: - - - $h = 0.20$ m; - . . - $h = 0.10$ m; — $h = 0.05$ m. Note higher values than 35 dB are not reached with single layers.

11 REDUCTION ALONG THE PATH

Besides noise from valves, also noise created by a high-speed (>40 m/s for gases) turbulent flow in a pipe must be considered. However, in practice, pipe noise will only exceed valve noise at gas velocities at the valve's outlet exceeding 0.3 Mach for standard trims and 0.2 Mach for low noise trims.¹⁸ The internal sound power (dB re 1 pW) created by the turbulent boundary layer in a straight pipe is according to VDI 3733¹⁵ given by

$$L_{W+}(f) = 20 - 0.16U + 10 \log_{10}(A \times P \times U^6) - 25 \log_{10} \frac{NT}{N_0 T_0} - 15 \log_{10} \frac{\gamma}{1.4} - 15.5 \log_{10} \frac{f}{U} \quad (4)$$

where A is the cross-sectional area of the pipe (in m^2), P is the static pressure (in Pa) normalized with the reference pressure 100 kPa, U is the flow speed (in m/s), N is the gas constant ($N_0 = 287$ J/kg K), T is the absolute temperature ($T_0 = 273$ K), γ is the specific heat ratio, and f is the octave band midfrequency (in Hz). The formula is valid in the range $12.5 \leq f/U \leq 800$.

In addition, bends and regions with flow separation, for example, area expansions, can represent important sources of flow-induced noise. To avoid excessive flow separation and noise generation expansions (from

the valve outlet to the pipe) should be in the form of conical sections with an angle not exceeding 15° , except where gas exit velocities at the valve outlet exceed Mach 0.3. Bends should also be separated from the outlet jet ($> 5D_j$) of a valve to avoid a strong excitation of wall vibrations and sound radiation. It can also be noted that bends will have a higher sound transmission than a straight pipe section of the same diameter and wall thickness due to mode conversion.

For a given internal sound power in a pipe the radiated sound depends on the sound reduction index of the pipe wall. A representative value^{19,20} for the sound reduction index in the midfrequency range between f_{c1} (the 1st coincidence frequency) and f_r (the ring frequency), where maximum transmission occurs, is given by

$$R'_W = 10 + \log_{10} \frac{\rho_w c_L t_w}{\rho_f c_f D_i} \quad (5)$$

where D_i is the inner diameter, ρ_w is the density of the wall material, ρ_f is the density of the fluid, t_w the thickness of the wall, c_f is the speed of sound in the fluid, and c_L is the longitudinal wave speed in the wall. From this equation it follows that an increase of the wall thickness with a factor 2 will reduce the radiated sound pressure level by 3 dB. The IEC procedure predicts a larger influence of the wall thickness with an increase up to 6 dB per doubling of wall thickness. It

follows that changing the wall thickness is not a very efficient way of reducing the radiated sound. Instead so-called acoustic lagging is preferable when large reductions (>10 dB) are needed.^{21–23} This basic idea is similar to a vibration isolation and aims at shielding the original pipe with a structure that has a reduced vibration level. This is done first by wrapping the pipe with a porous material (mineral wool) and covering this with a limp and impervious top sheet. The porous material provides sound absorption together with the enclosed air stiffness and damping. The damping is important to reduce the effect of acoustic modes between the pipe wall and the top sheet. The porous material used should have a high flow resistivity (> 20 Rayl/cm) and a low modulus of elasticity ($E < 0.15$ MN/m²).

Assuming that the top sheet is mass controlled the reduction in the radiated sound pressure level, for frequencies above the fundamental mass–spring resonance, will be¹⁵

$$\Delta L_p \approx \frac{40}{1 + 0.12/D_0} \log_{10} \left(\frac{f}{2.2f_0} \right)^2 \quad f > f_0 \quad (6)$$

where f is the frequency (Hz), f_0 is the mass–spring resonance frequency (Hz), and D_0 is the outer diameter (m) of the pipe (without lagging). The mass–spring resonance can be calculated from

$$f_0 = 60 \sqrt{\frac{m_t'' + m_p''}{m_t' m_p' h}} \quad (\text{Hz}) \quad (7)$$

where m'' is the surface mass (kg/m²), the superscript t denotes the top sheet and p the pipe, and h is the thickness (m) of the porous (air-filled) layer. Equation (6) has been plotted in Fig. 9, assuming pipe walls that are much heavier than the top sheet and with diameters > 0.12 m. In practice, using a single-walled lagging a maximum reduction of 30 to 35 dB can be reached. Higher values can be reached in particular in the high-frequency range by using double-walled designs.

In gas-filled systems silencers can also be used to reduce radiated noise from the downstream side of a valve and also at its upstream side, since a good portion of the sound power generated at the valve's interior will escape upstream (typically 10 dB less the downstream). This is especially prevalent for “line-of-sight” valves such as butterfly or ball valves. It is then important that the silencer is positioned as close as possible to the valve or the upstream end of a pipe from which radiation is to be reduced. There are two basic types of silencers: reflective and dissipative, see also Chapter 85. Reflective silencers create a reflection of waves by an impedance mismatch, for example, by an area change or a side-branch resonator. The reflective silencer type is primarily intended for the plane wave range and is efficient for stopping single tones. Dissipative silencers are based on dissipation

of acoustic energy into heat via porous materials such as fiberglass or steel wool. These silencers are best suited for broadband sources and for the mid- or high- frequency range, which means that dissipative silencers are best suited for reducing valve noise.

CHAPTER 76

HYDRAULIC SYSTEM NOISE PREDICTION AND CONTROL

Nigel Johnston

Department of Mechanical Engineering
University of Bath
Bath, United Kingdom

1 INTRODUCTION

This chapter focuses on high pressure hydraulic fluid power systems using positive displacement pumps. In such systems line diameters are generally relatively small (typically 10 to 50 mm). The flow is generally considered to be single phase (quantities of gas bubbles or solid particles are negligible), and pressures are typically up to 100 to 300 bars. These systems have a reputation for often producing unacceptably high levels of noise. This problem can limit the range of applications of fluid power and often causes the system designer to favor other means of power transmission. However, there are several measures that can be taken for noise reduction.

Airborne noise originates from vibrations of components, pipeworks, and housing. This vibration or *structure-borne noise* may be caused directly by the mechanical action of pumps and motors and can be transmitted from pumps through mounts, driveshafts, and pipes. Structure-borne noise may also arise from system pressure ripple or *fluid-borne noise*. Fluid-borne noise is caused primarily by unsteady flow from pumps and motors but sometimes from valve instability, cavitation, or turbulence. Fluid-borne noise can be transmitted long distances through pipework.

2 POSITIVE DISPLACEMENT PUMP FLOW RIPPLE AND NOISE

The prime sources of noise in a hydraulic circuit are usually the pumps and motors, although valves are also important noise generators.¹⁻⁴ In addition, prime movers can be noisy; diesel engines produce high noise and vibration levels, and electric motors generally have fan cooling systems that produce noise.

Pumps for fluid power applications are generally positive displacement devices. The most common types are piston pumps, gear pumps, and vane pumps, and there are several variations for each type.⁵ The following discussion also applies to hydraulic motors, which work in a similar way to pumps.

Positive displacement pumps tend not to produce an absolutely steady flow rate. Instead, the flow consists of a mean value on which is superimposed a flow ripple. The magnitude of the flow ripple is dependent upon the pump type and operating conditions but usually has a peak-to-peak amplitude of between 1 and 10% of the mean flow rate. Pump flow ripple tends to have a periodic waveform due to the cyclic nature

of a pump's operation, and different classes of pump have different characteristic flow ripple waveforms. This flow ripple interacts with the characteristics of the connected circuit to produce a pressure ripple. There are methods available for measuring pump flow ripple and fluid-borne noise characteristics. See, for example, Ref. 6 and 7.

Flow ripple occurs in both the suction and the discharge lines. Normally, the discharge flow ripple is most important in terms of noise. However, fluid-borne noise in the suction line may cause noise problems especially when it causes vibration of the reservoir. The large surface area of the reservoir may act as a "loudspeaker."

2.1 Flow Ripple from an Axial Piston Pump

Axial piston pumps are commonly used in high-performance applications as they can have variable capacity and can operate at very high pressures. A simplified cross section of an axial piston pump is shown in Fig. 1. A rotating cylinder block is attached to the shaft, and an angled swash plate causes the pistons to reciprocate. At the other end of the cylinders is a fixed port plate to provide communication between the cylinders and the inlet and outlet ports.

Consider first of all the flow that is produced by an idealized single cylinder. The piston moves sinusoidally, and the port plate is arranged so that the cylinder communicates with either the suction or

Figure 1 Simplified cross section of an axial piston pump.

discharge port, depending on the direction of motion of the piston. First, we will assume that the cylinder switches from one port to the other at exactly top dead center (TDC) and bottom dead center (BDC), and ignore fluid compressibility. The flow from the cylinder into the discharge will be equivalent to half a sinusoid as shown in Fig. 2. This is termed the *kinematic* component as it is determined purely from geometric considerations.

In reality, however, as the piston passes BDC and the discharge port opens to the cylinder, the difference between the high-pressure discharge and the low pressure in the cylinder causes a reverse flow into the cylinder until the pressure equalizes. This can take the form of a sharp spike as shown in Fig. 2. The amplitude of this spike is pressure dependent and it can be quite large. Fluid inertia in the port plate can cause oscillations after the spike as shown in the figure. A similar effect will occur in reverse as the cylinder passes TDC and opens to the inlet port.

The total flow ripple from a multicylinder pump is the sum of individual cylinder flows. Usually, the main feature of the flow ripple is the flow spike due to fluid compression, which can lead to severe system noise. This repeats itself for each cylinder; a nine-cylinder pump will have nine spikes per revolution. The magnitude of the flow ripple from axial piston pumps is strongly dependent on the design of the pump, in particular the port plate geometry. Fig. 3 shows some measured flow ripples for a piston pump⁵ (the plots are offset vertically for clarity). The compression pulse is clearly apparent and its magnitude is roughly proportional to pressure.

The flow ripple can be reduced by use of carefully designed relief grooves in the port plate as shown in Fig. 4. These have the effect of slowing down the compression of the fluid in the cylinders and making the reverse flow spike less severe, as Fig. 5 shows. Most pumps of this type make use of this feature.

Retardation of the opening of the port plate can also reduce the flow ripple. In this way, the piston motion can be used to precompress the fluid in the cylinder to the delivery pressure before the delivery port opens. This can be very effective as shown in Fig. 5, but

Figure 2 Flow from a single cylinder.

Figure 3 Measured piston pump flow ripple.

Figure 4 Axial piston pump relief grooves.

Figure 5 Typical flow ripples for different port plate configurations.

the optimum delay depends on the load pressure, swash setting, and fluid properties. Most pumps have a combination of relief grooves and retarded ports. Adjustable delays have been tried, but this can be very complicated to implement successfully.

The fundamental frequency is equal to the *pumping* frequency, that is, the speed of the pump (in revolutions/second) times the number of pistons, gear teeth, or other pumping elements. A typical plot of the flow

ripple harmonic amplitudes for an axial piston pump is shown in Fig. 6. The “spiky” nature of the flow ripple waveform is manifested in a large number of strong harmonics over a broad frequency range.

2.2 Flow Ripple from Vane Pumps

Vane pumps incorporate a slotted rotor and a eccentric or oval cam ring. Flat metal vanes slide in the rotor slots and bear against the cam ring as shown in Fig. 7.

The flow ripple from vane pumps has similar features to that from axial piston pumps. The flow ripple depends on the shape of the cam ring, but

Figure 6 Typical piston pump flow ripple spectrum.

Figure 7 Simplified diagram of a vane pump.

generally the dominant component is produced by fluid compression as a vane passes the start of the delivery port. This can be made more gradual by the use of relief grooves. The magnitude of the flow ripple tends to be increased if cavitation or air release occurs because of increased fluid compression. Hydraulic power-assisted steering systems often use engine-driven vane pumps with integral flow and pressure control valves, in which the excess flow is bypassed internally through a valve from the pump delivery back to the intake. Cavitation or air release can occur in the bypass valve, resulting in gas bubbles being recirculated through the pump.

2.3 Flow Ripple from Gear Pumps

External gear pumps consist of two meshing gears in a housing. Fluid is pumped via the gaps between the gear teeth. The idealized form of the source flow ripple from an external gear pump is shown in Fig. 8. It is due to the changing geometry of the meshing of the gears as they rotate. It is generally assumed to be independent of pressure. Fluid compression, although it does take place between the inlet and outlet ports, normally tends to be less sudden as it is spread over a large angle of gear rotation and is therefore not as significant as for axial piston pumps.

The spectrum of this flow ripple consists of a very strong fundamental component and rapidly diminishing higher harmonics, as shown in Fig. 9. This can result in a quite different audible tone to that of a piston or vane pump.

Several attempts to produce low noise external gear pumps have been made, such as using helical gears or multiple, phased gears, or by reducing the gear backlash. However, these all incur a cost penalty.

2.4 Reduction of Pump Flow Ripple

The noise problem is tackled at its true source by reducing the flow ripple of the pump or motor. However, this cannot normally be controlled by the user except by changing the operating conditions. Reducing pressure can help but is generally not practical.

Figure 8 Ideal gear pump flow ripple.

Figure 9 Typical gear pump flow ripple spectrum.

Air bubbles in the fluid can increase the fluid compressibility and hence increase pump flow ripple. Good reservoir design and suction line design can minimize air bubbles and air release.

Cavitation is the formation of bubbles of vapor that occurs in regions where the pressure falls to the vapor pressure of the liquid (the vapor pressure is typically about 100 to 1000 Pa absolute). Cavitation can increase pump noise, as well as being highly damaging. The cavitation can be directly audible either as a hissing or a harsh rattle. Additionally, cavitation releases air bubbles in the fluid. Cavitation can be avoided by good inlet line design or the use of a boost pump if necessary.

Selection of a different pump with less flow ripple may be a solution to a noise problem. Cost must, of course, be taken into account. Classes of pumps that generally produce low flow ripple include internal gear pumps and screw pumps. Screw pumps are used in submarines precisely because of their low noise, but rarely used elsewhere because of their cost. Pumps with high-flow ripple include external gear pumps and axial piston pumps. Generally, there are several other criteria that also need to be considered, and it is rarely possible to select a particular class of pump purely on the basis of its noise characteristics. Also, different pumps of the same class can produce radically different fluid-borne noise levels (Table 1).

3 VALVE NOISE

Valves can cause noise in a number of ways:

- Cavitation, air release, and turbulence

- Chatter or instability
- Water hammer

3.1 Cavitation, Air Release, and Turbulence Noise

Cavitation frequently occurs in valves where it causes a distinct high-frequency hissing noise. The random nature of the bubbles causes a broadband spectrum. Flow and pressure control valves contain variable orifices to control the fluid flow. An orifice acts to restrict the flow causing a high-velocity jet. Bernoulli's equation states that the sum of static pressure and dynamic pressure is constant (if losses and gravity are neglected). The dynamic pressure is proportional to the square of the fluid velocity. In a high-velocity jet the dynamic pressure is high and hence the static pressure is low. Most of the dynamic pressure is dissipated through turbulence and viscous losses downstream of the orifice, but some may be converted back to static pressure when the jet slows down. This means that the pressure in the valve can be less than the downstream pressure. Also intense turbulence can occur around the jet, causing localized, unsteady low-pressure regions. Cavitation can occur if the localized pressure falls to the vapor pressure. Air release may also occur.

Some valve types are more prone to cavitation and turbulence noise than others. Laminar flow valves have been designed that avoid turbulence; however, the flow characteristics of these tend to be strongly dependent on the fluid viscosity and hence on temperature.

Cavitation is strongly influenced by the back pressure downstream of the valve. Often cavitation noise can be reduced by increasing the back pressure. One way of achieving this is to use two valves in series. Unfortunately, increasing the back pressure can sometimes have the converse effect of worsening cavitation noise, as cavitation noise tends to reach a peak at a certain back pressure and falls for lower or higher pressures.⁸

Table 1 Comparative Noise Levels of Typical Pumps

Noisiest	Axial piston pumps
.	External gear pumps
.	Vane pumps
.	Internal gear pumps
Quietest	Screw pumps

3.2 Valve Instability

Some valves can generate self-excited oscillations, which results in a squealing or whistling sound, sometimes very loud. This is an inherent feature of the valve and may be due to a combination of low damping, positive feedback, jet oscillation, and resonance. It tends to be highly dependent on pressure, flow, and temperature and sometimes comes and goes for no apparent reason. In some cases it can be eliminated easily by small changes in valve position or conditions, but in other cases it is more tenacious and may be avoided only by use of a different component.

3.3 Water Hammer

Water hammer⁹ is a common name for hydraulic shocks or surges that usually occur when a valve is suddenly opened or closed. When a valve is closed the fluid is decelerated suddenly, causing a pressure rise at the inlet and fall at the outlet due to the momentum of the fluid. This results in a pressure wave that travels at the speed of sound through the pipelines (the speed of sound in hydraulic fluid is typically 1000 to 1400 m/s, considerably higher than in air). The wave is reflected when it reaches a valve, pump, reservoir, or other change. Cavitation can occur if a low-pressure wave is formed. Water hammer can cause severe transient vibration and “banging”. As well as causing noise, it can be damaging to the system. Water hammer is best avoided by preventing sudden valve closures. In severe cases shock alleviators such as accumulators can be used.

4 TUNING OF THE CIRCUIT TO AVOID RESONANT CONDITIONS

It may be helpful to understand the behavior of pressure waves as they travel in a hydraulic circuit. Consider a simple system consisting of a pump, a pipe, and a restrictor valve. The pump produces a flow ripple that consists of a broad spectrum of harmonic components. We shall examine what happens to one

single harmonic (i.e., a pure sinewave) of this flow ripple.

The sinusoidal flow ripple harmonic produces a pressure wave that travels along the pipe at the speed of sound. When the wave reaches the other end of the pipe, it is reflected and travels back to the pump. It is reflected again at the pump, where it combines with the original wave. It may combine so as to reinforce the original wave, in which case high-pressure ripple levels can build up. This is a resonant condition. Alternatively, it may combine so as to partially cancel out the original wave, resulting in much lower pressure ripple levels. This is an antiresonant condition. Whether resonance, antiresonance, or something in between occurs depends on the length of the pipe and the frequency.

For the simple pump–pipe–restrictor system, the length of pipe has a great effect upon the pressure ripple levels. This also applies to more complicated systems. Thus by judicious system design, it may be possible to cause a significant reduction in the pressure ripple levels. However, for this to be done in a rational manner, detailed knowledge of the relationships between the circuit configuration and fluid-borne noise is required. For all but the most trivial of systems this relationship is not simple.

For example, Fig. 10 shows a graph of the simulated root-mean-square (rms) pressure ripple at the pump exit in a typical hydrostatic transmission consisting of a piston pump, a length of flexible hose, a length of rigid pipe, and a motor for a range of different rigid pipe lengths. Only the pressure ripple pump flow ripple is considered in this simulation; the motor is modeled as a passive termination. It can be seen that there is a very large variation in the simulated pressure ripple levels, and resonant peaks are apparent.

Some specialist software packages are available for prediction of fluid-borne noise levels.^{10,11} These can aid the designer in determining what circuit dimensions

Figure 10 Example of simulated pressure ripple magnitude in a hydrostatic transmission versus pipe length.

will cause resonance, so that steps can be taken to avoid these conditions. Alternatively, trial-and-error can be used. Tuning of the system is most likely to be effective when the speed of the pump is fixed, as it is difficult to avoid resonances if the harmonic frequencies are varying.

5 FLUID-BORNE NOISE SILENCERS OR PULSATION DAMPERS

A wide range of proprietary fluid-borne noise silencers (attenuators, pulsation dampers) is available. These, when used correctly, can be extremely effective in reducing the fluid-borne noise in a circuit, reductions of 20 to 40 dB (10:1 to 100:1) being typical. Specialized silencers tend to be expensive, and may be bulky and heavy, requiring robust supports. They normally are only suitable for situations in which the fluid-borne noise level is very critical and where cost, size, and weight are less important, such as in naval vessels. However, other common hydraulic circuit components such as accumulators and flexible hoses may be effective as fluid-borne noise silencers and provide a low-cost solution.

Figure 11 shows some common silencers and Fig. 12 shows their attenuation characteristics. This is described by the *transmission loss*, which is the ratio of the input fluid-borne sound power to the output fluid-borne sound power under controlled conditions, normally expressed in decibels.

The side branch and Helmholtz resonators (Fig. 11a and 11b) are tuned devices and only provide good attenuation over narrow bands, which limits their range of applications. Both are effective at their resonant frequencies at which they have a low entry impedance. Side branch resonators are sometimes known as quarter wavelength resonators, as the lowest frequency at which this happens is when the resonator length is a quarter of the wavelength, that is,

$$f = \frac{c}{4L} \text{ Hz}$$

where $c = \sqrt{B/\rho}$, is the speed of sound in the fluid (in m/s), B is the effective bulk modulus of the fluid (in N/m²), ρ is the fluid density in (kg/m³), and L is the tube length. Attenuation bands also exist at odd integer multiples of this frequency (i.e., $3c/4L$, $5c/4L$, etc.), as shown in Fig. 12a. These can be used to attenuate several harmonics produced by a pump or motor, but it is not possible to attenuate a complete harmonic series; it can be tuned to the first, third, and other odd harmonics but not simultaneously to the even harmonics.

The speed of sound is typically about 1000 to 1400 m/s, but it depends on pressure and temperature and can be considerably reduced by air bubbles or by flexible tube walls. For this reason it can be difficult to tune such a device accurately. Care should be

Figure 11 Some fluid-borne noise silencers: (a) Side branch; (b) Helmholtz resonator, (c) accumulator, (d) expansion chamber, and (e) typical double chamber silencer.

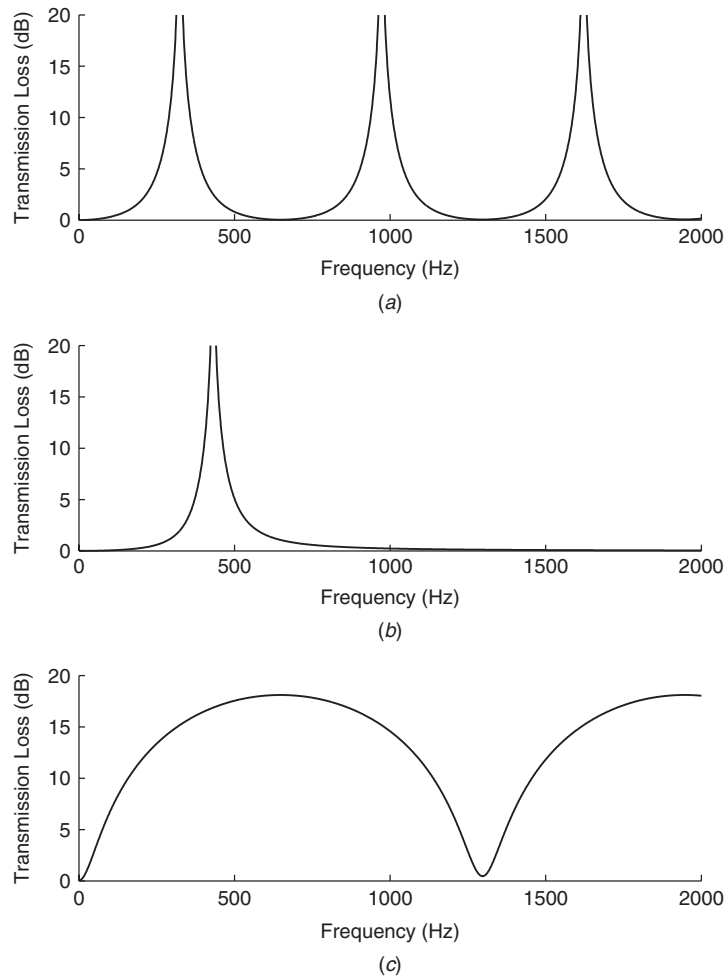

Figure 12 Silencer performance characteristics: (a) Side-branch resonator, $L = 1$ m, $C = 1330$ m/s; (b) Helmholtz damper, $V = 0.5$ L, $A = 1\text{ cm}^2$, $L = 5$ cm; (c) expansion chamber, $L = 0.5$ m, area ratio = 16.

taken to avoid trapped air; for example, it should be positioned pointing downward to allow bubbles to escape by buoyancy. If flexible hose is used for the side-branch resonator, allowance must be made for the compliance of the hose, which can reduce the effective bulk modulus by a factor of between 2 (for a stiff, high-pressure hose) and 10 (for a lower pressure textile-braided hose). In addition, the higher frequency attenuation bands may not be uniformly spaced in frequency because of the complex hose behavior.

A Helmholtz resonator has a single resonant frequency given by

$$f = \frac{c}{2\pi} \sqrt{\frac{A}{VL}} \quad \text{Hz}$$

where A is the cross-sectional area of the neck (in m^2), V is the volume of the chamber (in m^3), and L is

the length of the neck. The attenuation characteristics are shown in Fig. 12b. The liquid volume acts as a capacitor or spring, and the fluid in the neck as an inductor or mass. Similar considerations apply as for side-branch resonators.

The accumulator (Fig. 11c) behaves in a similar way to the Helmholtz damper. Because of the low stiffness of the gas, it generally has quite a low resonant frequency, and this depends strongly on pressure as the gas volume and stiffness changes. Standard accumulators are not particularly effective as high-frequency attenuators, although special types are available for this purpose. One silencer design based on the accumulator principle utilizes a tubular diaphragm through which the hydraulic fluid flows, with pressurized gas in an annular chamber surrounding the diaphragm. Because the neck of the accumulator is eliminated from this design, it can be very effective as a silencer. However,

the gas precharge pressure is critical, and it may not be effective or reliable in applications where the hydraulic pressure varies greatly. It will also require more regular maintenance than a simple expansion chamber.

The expansion chamber (Fig. 11*d*) consists of an in-line chamber (usually cylindrical) with a larger diameter than the connected pipes. It has the attenuation characteristics shown in Fig. 12*c*. It has a broadband behavior, apart from narrow bands of poor attenuation at frequencies given by

$$f = \frac{c}{2L} \text{ Hz}$$

where L is the chamber length. The peak transmission loss (TL) is given approximately by^{1,9}

$$TL_{\text{MAX}} = 20 \log_{10}(r) - 6 \text{ dB}$$

where r is the ratio of expansion chamber cross-sectional area to line cross-sectional area.

Expansion chambers are ineffective at very low frequencies. The lowest cutoff frequency, below which the transmission loss is less than 3 dB, is given approximately by

$$f_0 = \frac{c}{\pi L r} = \frac{Ac}{\pi V} \text{ Hz}$$

where A is the line cross-sectional area and V the expansion chamber volume. Thus, for good low-frequency attenuation a large volume chamber is needed.

Commercial silencers as shown in Fig. 11*e* tend to be combinations of expansion chambers, side-branch resonators, Helmholtz dampers and orifices, and can be very effective over a broad frequency range, typically providing broadband attenuation of 30 dB or more. However, they can be bulky and expensive, particularly if they are to be effective at low frequencies.

6 FLEXIBLE HOSE

Flexible hose is often a convenient and cost-effective way of attenuating or isolating both fluid-borne and structure-borne noise. A suitable length of flexible hose should be fitted close to the noise source to reduce noise and vibration in the rest of the system.¹⁻³ In providing mechanical isolation for a pump, it is essential to use flexible hoses for both suction and delivery. Depending on the relative importance of quietness and other factors such as cost and compactness, hose lengths are likely to vary from about 1 m to around 3 m.

If the pipework can be firmly clamped to a support of high impedance at the point where it is connected to the hose, this will improve the isolation.

While flexible hose is very effective at isolating structure-borne noise, it is not always so effective for reducing fluid-borne noise. Typical measured fluid-borne noise transmission loss characteristics of 1 m lengths of several common hose types are shown in Fig. 13. The nylon-braided hose provides a useful level of attenuation over a broad frequency range. This hose was designed for a power-assisted steering application and is limited to pressures below about 80 bars. The single steel-braided, double steel-braided, and four-spiral steel hoses, which have much higher pressure

Figure 13 Typical fluid-borne transmission loss characteristics of 1 m of flexible hose.

ratings, have poor transmission loss characteristics except in narrow frequency bands. The transmission loss is especially poor at low frequency.

The nylon-braided hose is far more expandable and compliant than the steel-reinforced hoses. It is this expandability, along with the inherent damping of the rubber and reinforcement, that provides fluid-borne noise reduction. High-pressure steel-reinforced hoses do not provide much attenuation, and hose may not be very effective for reducing fluid-borne noise produced by a high-pressure pump. However, the hose will still provide useful structure-borne noise isolation.

For fluid-borne noise attenuation, generally speaking the more hose the better. However, it is possible to use too much hose because:

- Hose is expensive compared with rigid pipe, and long lengths may not be cost effective.
- For a given level of fluid-borne noise, the more flexible walls of hose will radiate more airborne noise per metre length than an equivalent steel pipe.

6.1 Tuner Inserts for Hoses

In hydraulic power-assisted steering systems, flexible hoses are used as the main noise attenuation device. Highly compliant textile-braided hoses are generally used, as these provide good vibration isolation and noise reduction and the pressures are usually relatively low (<100 bars). To improve the fluid-borne noise attenuation further, tubular “tuner” inserts are often fitted inside the hose as shown in Fig. 14. These usually consist of a flexible metal or plastic tube attached inside one end of the hose and provide a form of tuned attenuator. The plastic tubes may be perforated to improve the performance. Sometimes restrictors and sleeves are used in conjunction with the tubular insert. Tuner inserts can provide excellent attenuation at low cost but need to be “tuned” carefully to the system.^{12,13} To be effective these devices rely on compliant hoses and are likely to be less effective in higher pressure systems because stiffer hoses are needed.

7 VIBRATION ISOLATION

Isolating the mechanical vibration of a pump from the foundation on which it is mounted is achieved using

flexible mounts. There are two basic types of arrangement: The pump and driving motor can be mounted separately and connected by sufficiently flexible couplings, or they can be rigidly connected together and the combined unit can be flexibly mounted. The former method is not usually recommended. Misalignment is inevitable and, even with flexible couplings, this can put loads on the bearings of the pump and motor, which are undesirable and may themselves generate vibration. The only circumstance in which separate mounting should be considered is when transmission of the pump vibration to the motor causes unacceptable radiation of noise from the much larger surface area of the latter. Even then, an acoustic enclosure or cladding may be the best answer.

Normally, the pump is connected to its driving motor either by a bell housing or by having both the pump and the motor on a common base. The surface area of a base should be as small as possible to minimize airborne noise radiation; the base should be as rigid as possible, and in the case of both the base and the bell housing it is an advantage to choose materials and construction to give some damping, for example, by using cast iron or by using a bolted or riveted construction. Thin rubber gaskets can be helpful on a bell housing. The worst type of base would be a flat plate, which would act as an effective sounding board.

Even with a combined mounting arrangement, care needs to be taken in the selection and fitting of a suitable shaft coupling between pump and motor. This should incorporate a resilient material, but the torsional stiffness should not be such as to allow torsional resonances in the operating range. Accurate alignment is desirable.

Because of their small surface area, pipes are not usually strong sources of airborne noise, but problems tend to occur when pipes are mounted incorrectly. A pipe attached rigidly to a metal surface can produce a very effective loudspeaker! Flexible plastic or rubber mounts should be used, as their resilience reduces the transmission of vibration from the pipe and also damps out resonances in the pipe. The mounts should be located at stiff points in the supporting structure, and not in the middle of panels.

8 ACOUSTIC ENCLOSURES AND CLADDING

Enclosure of a hydraulic system¹⁻⁴ within a sound barrier can be a very effective means of noise

Figure 14 Hose with tuner insert.

reduction. It may be feasible to enclose the "power pack" (pump, prime mover, reservoir, and ancillary components) within a chamber, but it is rarely possible to enclose the complete hydraulic system. Often this is sufficient as the power pack may be the prime source of airborne noise. However, pipes are very effective conductors of fluid-borne noise, and structure-borne noise and it may not be practicable to enclose these and the rest of the circuit. Flexible hose is usually necessary to provide isolation in both supply and return lines.

Great care must be taken when enclosing the power pack to prevent overheating. In particular, a free airflow path must be provided for electric motor cooling. Baffled ducts are needed to limit the escape of noise through the vents. Apart from the vents, the enclosure must be well sealed as small gaps can seriously impair the performance of the enclosure. Easy access must be included to facilitate regular maintenance.

It is very important that the hydraulic components or other vibrating parts do not touch the acoustic enclosure, as the enclosure will act as a sounding board and make the problem worse. Particular care should be taken where pipes enter or leave the enclosure.

9 CONCLUSIONS

Noise in hydraulic systems is a broad and complex subject. The noise level of a system is dependent on the complex interaction of a large number of components. Pump flow ripple causes fluid-borne noise that then causes structure-borne and airborne noise. There are several established methods for reducing noise, and with some care significant improvements can be made with little or no increase in cost.

1 INTRODUCTION

A combustion system is composed of a burner in which fuel is added to the air or pure oxygen stream and a combustor or furnace that encloses the reaction zone. In furnaces and burner systems, heat chemically stored in the fuel is released, providing an increase in temperature of the working medium ranging from 1000 K up to 3000 K. The temperature increase depends on the fuel enthalpy.

Furnace and burner applications range from domestic heating units to power generation central station boilers to gas turbine engines and use solid, liquid, and gaseous fuels. Due to their high heat release density, furnace and burner applications are prone to combustion instabilities. The principles of combustion noise in industrial and power systems using gas and liquid fuels apply generally to all types of combustion systems. The phenomenon of thermoacoustically induced oscillations in combustion systems is complicated and usually only qualitative explanations can be given. Various prediction methods have been developed in the past decade. Technical solutions are available to damp and control combustion oscillations.

2 OVERVIEW OF COMBUSTION SYSTEMS

Combustion systems consist of fuel and air delivery systems, a burner, and a combustor. The fuel injection element is typically referred to as the burner. The element within which heat release takes place is typically referred to as the combustor or furnace. The elements of a simplified premix combustion system are shown in Fig. 1.

The purpose of combustion systems is to add heat to an airstream. The power density of combustion systems ranges from approximately 100 kW/m³ in atmospheric systems to 100 MW/m³ in modern stationary gas turbines operating at pressurized conditions and as

Figure 1 Main elements of premix combustion systems for (a) an ideal premix system and (b) a technical premix system.

high as 500 MW/m³ in jet engines operating at pressures up to 40 bars. The main mechanisms for combustion noise are common to all combustion systems.

The purpose of a fuel burner is to mix and direct the flow of fuel and air to ensure rapid ignition and complete combustion within the furnace or combustor. The combustion of gaseous fuels takes place in two ways: (1) when the gas and air are mixed before ignition, as in a Bunsen burner, referred to as premix flames (Fig. 1 depicts both ideally premixed and technically premixed cases) and (2) when the gas and air are mixed after the fuel has been heated, referred to as diffusion flames.¹

In diffusion mode the fuel and oxidizer enter the reaction zone separately and diffuse through it. Combustion takes place at stoichiometric conditions

and is typically stable and high in temperature, causing high levels of oxides of nitrogen emissions (NO_x). Premix mode is characterized by lower combustion temperatures, permitting NO_x emissions as low as 9 ppm for pressurized gaseous combustion and below 2 ppm for atmospheric gaseous combustion. Premix systems utilizing liquid fuel have first to evaporate the liquid droplets, then to mix them with the air prior to combustion.² Solid fuels such as coal can only be burned in diffusion mode with combustion taking place on the surface or in the core of the solid particle, requiring other measures for NO_x abatement.

Flame stabilization or anchoring consists of an equilibrium condition established between the heat release rate or reaction rate of the reacting species and the flow velocity. This equilibrium is maintained by providing flow recirculation zones and/or piloting, which provides a small region of high temperature at which reaction of main flow can be anchored. In case of low turbulent flow the heat transfer by conduction and radiation toward the cooled walls also affects this equilibrium.

Swirl, imparted by the burner, is commonly used to augment flame stabilization by forming large reverse flow zones with resultant increased mixing rates. In premix burners the flow velocity must be high enough to avoid flashback into the burner but not so high as to cause blowoff at the burner outlet, extinguishing the flame.^{3,4}

Noise generated by the combustion process can generally be characterized as one of two types: (1) combustion roar and (2) combustion-driven oscillations or thermoacoustic instabilities. The latter type of noise is observed when pressure oscillations are induced by heat release oscillations. The term thermoacoustic reflects the strong relationship between heat release oscillations and pressure oscillations that can establish a feedback cycle as shown in Fig. 2.^{5,6} Although thermoacoustic instability is closely connected to flame stabilization, their instability criteria are different. In this chapter the main focus is on thermoacoustic instability owing to its higher sound pressure levels and greater potential for structural damage.

3 TYPES OF COMBUSTION SYSTEMS

Premix burners are used for many natural-draft and forced-draft applications where accurately controlled conditions must be maintained. Natural-draft premix burners use fuel spuds (jet orifices) and injectors to aspirate the air into a mixing volume that forms a

Figure 2 Simplified feedback cycle that generates thermoacoustic combustion instability.

portion of the burner. An adjustable shutter may be included for the control of the air flow rate in an aspirated-air burner. Alternately, premix burners for use with forced air may aspirate the fuel gas.

Nozzle-mix burners mix the air and gas within the furnace or combustor downstream of the burner itself. Jets of fuel gas and/or air produce turbulence that sustains the mixing process. Some nozzle-mix burners employ rotating spiders to increase turbulence.

Diffusion-flame burners are not commonly employed as primary burners for furnaces and combustors. In modern low-emissions combustors, diffusion flames serve only as pilot flames using in the range of 3 to 15% of the total fuel flow to initiate and/or sustain ignition of the primary burner flames.

The general category of *oil-fired burners* may include all liquid-fueled burners. Any differences in the nature of noise emissions from oil-fired burners relative to gas-fired burners probably arise either from the presence of two distinct flame regions within oil-fired burners, the primary and secondary flame, or from the inherently different fuel nozzle arrangements. The primary flame is where the lighter fractions of oil are heated to ignition temperature and is also the source of heating for the secondary flame, where the heavier fractions are burned. Some liquid fuels require additional preheating, and as for all fuels the maximum temperature must be carefully controlled to avoid excessive flame instability.

Low NO_x emissions can be achieved in oil-fired burners by adding water to the flame, either via separated water spray or by a water-fuel emulsion. Due to the evaporation heat and the high heat capacity of the evaporated water molecules, the combustion peak temperatures are lowered, and NO_x emissions are significantly reduced. However, the evaporation of water also represents a volume source that in resonance with the combustion chamber may amplify combustion oscillations considerably.

As a general rule, high-frequency (1 kHz and higher) sound emissions from oil fuel combustion tend to be higher than for gas fuel. At low frequencies (approximately 150 Hz and below, including infrasonic frequencies), oil fuel combustion tends to generate lower overall sound pressure levels. At all other midfrequencies, there is essentially no difference. Thus, audible airborne A-weighted sound pressure level from gas firing is expected to be quieter, whereas overall unweighted or C-weighted sound pressure level from oil firing may be expected to be quieter. Such differences, however, are seldom more than 2 to 5 dB.

Pulse combustors are combustion-driven, non-steady-flow devices in which the fuel is reacted intermittently. With inherently high-energy conversion efficiencies on gas or liquid fuel, these devices are being applied in a variety of commercial uses, including gas turbine combustors.⁷ Their inherently high noise levels, however, limit their use somewhat.

4 PHENOMENOLOGICAL DESCRIPTION OF COMBUSTION NOISE

The noise spectrum for combustion roar has a broadband "haystack" form similar to, but flatter than, that of noise

from a jet. There is a spectral peak frequency, which, for open turbulent flames, increases with the mean velocity and decreases with increasing diameter and fuel mass fraction.⁸ The basic noise source is the turbulent motion of the flame front. Levels of combustion roar are heavily dependent on the levels of turbulence in the flame.⁵ Typical efficiencies of conversion from chemical energy input of a burner to combustion roar sound power emission are in the range 10^{-8} to 10^{-5} . While combustion system enclosures typically attenuate this sound radiation, components of the combustion roar spectrum may be amplified at the natural frequencies of these enclosures, thus modifying the spectrum shape and increasing energy conversion efficiency.

Combustion-driven oscillations are characterized by a feedback cycle that converts chemical energy to oscillation energy as shown in Fig. 2 at an efficiency on the order of 10^{-4} . In general, a fluctuating flame produces a periodic but nonsinusoidal wave output of energy. Thermoacoustic oscillations in the form of dynamic pressure resonances will cause furnace or combustor liner vibrations that can only be tolerated within certain limits. Maximum permissible pressures will be unique to each design and typically will be a function of frequency. Excessive heat transfer to surfaces can produce structural softening or weakening and when combined with excessive pressure oscillations can yield disastrous consequences.

Pressure oscillations in the combustion chamber induce volume flow oscillations at the burner exit, which in turn cause fluctuations in the flow of reacting species toward the flame front, resulting in heat release oscillations. In nonideal premixed systems this pulsating flow of reactants couples with fluctuations in fuel concentration generated at the mixing location due to the unequal acoustical impedances of the air and fuel supply systems. It may be said that the air supply is acoustically soft (compliant) due to small pressure losses, whereas the fuel supply is acoustically

hard (stiff), characterized by a high-pressure drop. In liquid-fuel injection systems the fuel supply is considered incompressible.

The combustion instability criterion follows Lord Rayleigh⁹: In the absence of acoustic damping, a positive correlation of the pressure fluctuations p' and the heat release fluctuations q' results in combustion instabilities. The mathematical formulation of this criterion is the Rayleigh criterion:

$$R_{g,\text{norm}} = \frac{\int_t^{t+T_{\text{per}}} \int_{V_{\text{Hz}}} p'(\mathbf{r}, t) q'(\mathbf{r}, t) d\mathbf{r} dt}{\overline{pq} V_{\text{Hz}} T_{\text{per}}} > 0 \quad (1)$$

where \mathbf{r} is the position vector, t denotes time, p' and q' denote the steady components of pressure and heat release, V_{Hz} denotes the combustor volume, and T_{per} denotes the time period of the oscillation.

The combustion-driven oscillation feedback cycle is complicated by the interaction of the influence parameters shown in Fig. 3. A typical spectrum depicting the spikes due to pressure oscillations induced by thermoacoustic instabilities is shown in Fig. 4.

The acoustic waves at low and intermediate frequencies have long wavelengths compared to the transverse dimensions of the combustion system, and they propagate through all of the adjoining components. The dimensions and acoustic properties of the burner plenum impact the impedance of the burner exit, affecting the magnitude of pressure-induced volume flow fluctuations. The acoustic properties of the fuel lines determine the magnitude of fuel flow fluctuations at the fuel nozzles. The acoustic geometry of the combustor determines the shapes of the acoustic modes, which are also influenced by the acoustic boundary conditions at the combustor exit. The central player in the feedback cycle is the flame.

Figure 3 Thermoacoustically relevant influence parameters of the feedback cycle.

Figure 4 Typical spectrum of thermoacoustically induced pressure oscillations.

The spectra of thermoacoustically induced pressure oscillations may be divided into low-, intermediate-, and high-frequency regions. For example, in gas turbine practice these regions are approximately: 4 to 70 Hz, low-frequency dynamics (LFD); 70 to 700 Hz, intermediate-frequency dynamics (IFD); and 700 to 4000 Hz, high-frequency dynamics (HFD). In the gas turbine combustor spectrum of Fig. 4, the IFD and HFD regions exhibit typically pronounced frequency peaks, although the HFD region includes more broadband excitation in addition.

Low-frequency dynamics are caused by periodic flame extinction, which is the result of poor flame stabilization. The flame reactions are quenched in the first part of the oscillation period and are then reignited during the second part. The feedback cycle involving total quenching of the flame is characterized by long time constants, and, hence, only low frequencies are excited. The frequencies are so low that the corresponding mode shape is a bulk mode in which all pressure fluctuations have the same phase. This instability is suppressed by either decreasing the flow

velocity or increasing the size of the recirculation zone, providing low-velocity regions for flame stabilization.

Intermediate-frequency dynamics are characterized by standing waves in which fluid elements oscillate with different phase angles. Mode shapes may, for example, be first-order or second-order axial modes for can-type combustors in gas turbines as shown in Figure 5. In annular combustors, azimuthal mode shapes are excited as shown in Figure 5c.¹⁰ The feedback cycle between pressure and heat release oscillations for IFD is characterized by time constants in the range of 3 to 6 ms.

High-frequency dynamics are excited by a feedback cycle involving very small time constants (below 0.5 ms). In general, a large number of mixed mode shapes featuring axial, azimuthal, and radial dependence fit into combustors of all types at this frequency range as shown in Fig. 5b. Different modes excited in parallel result in a more broadband spectrum. Not much is known about the excitation mechanism due to the small time scales, which cannot be resolved with current measurement technologies. Future work using modern fast data acquisition systems allowing

Figure 5 Mode shapes for the different types of frequency ranges: (a) axial Mode, 300 Hz, (b) combined mode, 1700 Hz, and (c) annular combustor, second azimuthal mode, 200 Hz.

higher time resolution will provide more insight into these phenomena. However, since the performance of damping systems increases with frequency, HFD has been suppressed successfully by using dampers such as Helmholtz resonators.

5 THEORETICAL DESCRIPTION OF COMBUSTION OSCILLATIONS

Combustion instabilities are described by nearly the same equations for the propagation of the acoustic pressure and acoustic velocity as outlined in Part I of this handbook. Differences are due to the source term representing the heat release fluctuations. Assuming only small perturbation, the linearized transport equations for acoustic pressure and velocity are then formulated as⁴

$$\frac{\partial \mathbf{u}'}{\partial t} + (\mathbf{u}' \cdot \nabla) \mathbf{u}' + \mathbf{u}' \nabla \mathbf{u}' = -\frac{1}{\rho} \nabla p' \quad (2)$$

$$\frac{\partial p'}{\partial t} + \mathbf{u}' \cdot \nabla p' + \mathbf{u}' \cdot \nabla \bar{p} + \gamma(\bar{p} \nabla \cdot \mathbf{u}') + \gamma(p' \nabla \cdot \mathbf{u}') = (\gamma - 1)q' \quad (3)$$

Neglecting the impact of mean flow the equations are simplified to be

$$\frac{\partial^2 p'}{\partial t^2} - c^2 \nabla^2 p' = (\gamma - 1) \frac{\partial q'}{\partial t} \quad (4)$$

$$\frac{\partial \mathbf{u}'}{\partial t} = -\frac{1}{\rho} \nabla p' \quad (5)$$

6 PREDICTION METHODS

A number of different methods for solving thermoacoustic problems have been developed. Table 1 lists a

selection of solution methods sorted according to the type of equation and the corresponding assumptions to which they refer. In column 4 comments relating to treatment of boundary conditions and the flame are given. Most modern design tools cover the low-Mach-number and the low-amplitude range, where the linear acoustic assumptions are valid. Details of treatments of nonlinear phenomena are limited to special considerations as published by Dowling¹¹ and Culick¹² or the nonlinear phenomena are addressed using more powerful computing methods.^{4,13,14}

An elegant method to determine the thermoacoustic stability is the Galerkin method.^{12,15,21} Here the spatial dependencies of the acoustic properties are represented by mode shape functions (see Fig. 5), determined by solving the Helmholtz equation, while the time dependence of the amplitude function of the instability is obtained by solving ordinary differential equations. Since the transverse dimensions of many combustion systems are small with respect to the wavelength of the instability, solution methods have been developed treating one-dimensional propagating waves at LFD and IFD frequencies.

In general, the acoustic properties of different components are represented by transfer functions relating downstream to upstream acoustic properties. Large networks of a number of components can be created, requiring a large matrix solution. These methods have been widely developed and are already used for thermoacoustic design of modern combustion systems.^{17–20}

Efforts have been made to link the heat release oscillations due to acoustic forcing and equivalence ratio fluctuations to the pressure oscillations.^{4,22–29} Heat release fluctuations may also be amplified by coherent flow structures, which are generally periodic

Table 1 Literature Survey of Different Solution Methods

Group	Assumption	Name of Method	References	Comments
1	No assumption	Direct numerical simulation (DES) or large eddy simulation (LES)	4, 13, and 14	Very time consuming; special treatment for the flame; special treatment of acoustic boundaries
2	Nonviscous flow	Nonlinear solution	11 and 12	Limited to special cases
3	Low amplitudes, linear limit	Three-dimensional Galerkin method	12, 15, and 16	Careful treatment of the acoustic jump conditions
4	Low-frequency limit one-dimensional propagating waves	One-dimensional transfer function networks	17–20	
			18	Very universal functionality, however-restricted to 1D geometry
			19	

in nature.³⁰ Although the flame–vortex interaction is the subject of several recent publications,^{31–34} knowledge of the impact of design parameters on this amplification factor is limited.

7 PASSIVE MEANS FOR NOISE CONTROL

In general, there are two fundamental means of passive noise control available to burner designers: (1) reducing the combustion-induced source terms and (2) increasing the acoustical damping.

7.1 Reducing Noise Sources: Changing the Time lag; Fuel Staging Concepts

The most relevant parameters expressing the dynamic property of the flame are the injection time lag τ_i and burner time lag τ_b . They directly control the phase relation between heat release oscillations and pressure oscillations. The burner timelag τ_b , which expresses the time a fluid element needs to flow from the burner outlet to the flame front, can be altered by changing the burner exit geometry. A cylinder mounted on the exit of the burner can be used to locate the heat release zone further downstream.³⁵ Another option is to change the swirl momentum flux of the burner exit flow. Reducing swirl generally leads to a longer flame with a wider heat release distribution. Increasing the swirl momentum flux shortens the heat release zone. Other means of changing the flame location are to modify the fuel concentration profile at the burner exit of partially premixed operating systems and/or to use cooling air across the flame tube to impact flame stabilization.

Care must be taken here because the success of the modifications depends on the interaction with the acoustic environment, which will differ from case to case. Care must also be taken if fuel compositions are changed since they will have an impact on fuel–air mixing and hence on the fuel concentration profile. In addition, the laminar burning velocity may change, altering the location of the heat release zone.

Richards and Janus³⁶ point out the impact of changing the injection time lag τ_i on dynamics by moving the fuel injection position. More flexibility is obtained if the fuel can be injected at different locations characterized by different time lags τ_i . Then operational flexibility is achieved by changing the fuel split between stages at different operating conditions.^{36,37} If the combustion system provides flexibility to do so, the flame response can be changed by changing the fuel–air ratio, which determines directly the density jump condition in the heat release zone.³⁸ Another way to directly affect the flame response is to change the burner size³⁹ and/or burner exit velocity. Both changes will lead to a different size of the heat release distribution. Generally, a more widespread heat release distribution yields a lower excitation of pronounced frequencies.

In blast-furnace stoves featuring diffusion-type gas burner with acoustically soft air and/or fuel supplies, the fuel injection may be located at a pressure node of the combustion chamber to suppress combustion-driven oscillations.⁵ In addition, the length of the fuel

supply line can be modified to detune the system. This is consistent with other approaches applied to more complex gas-fired combustion systems such as gas turbines. Experiments involving tuning of the fuel line impedance have succeeded in suppressing pressure fluctuations.⁴⁰ Fuel line impedance adjustments may be even more promising if the fuel lines have low impedances as in syngas combustion systems. The impact of coherent structures may be reduced by increasing the turbulence level,³⁰ but doing so may also increase turbulence-induced combustion roar. Flame stabilization and hence dynamic flame response may also be affected by the heat transfer to an environment changing in temperature.⁴¹ That is the reason for different stability behavior of the burner during startup of the heater.

7.2 Resonators for Noise Control

Acoustic resonators can provide effective means for increasing the damping of selected modes. These devices may either be add-ons to existing apparatus or designed-in features of new equipment. In principle these devices resemble either simple Helmholtz resonators or quarter-wave tubes:

- A simple Helmholtz resonator is shown in Fig. 6. A small cavity is acoustically connected to the combustion chamber or furnace through an orifice.⁴² The fluid inertia of air or combustion gases residing in the orifice oscillates against the volumetric compliance of the small cavity at a well-defined natural frequency given by

$$f_0 = \frac{c}{2\pi} \sqrt{\frac{S}{V(\ell + \Delta\ell)}} \quad (6)$$

- A quarter-wave tube is also shown in Fig. 6, in which an elongated cavity length provides the fluid inertia in lieu of an orifice. The natural frequency of the quarter-wave resonator is given by

$$f_0 = c/4(L_R + \Delta\ell) \quad (7)$$

In the above formulas, $\Delta\ell$ is a length correction to account for the acoustic mass addition at the resonator opening. At low-pressure amplitudes it may be estimated as 0.85 times the diameter for a two-sided opening. A flow-through resonator configuration may also be employed, but the calculations are more involved.⁴³

The increment of damping added by a single resonator will be in proportion to its acoustic conductance at the frequency of the pressure waves and to the square of the pressure magnitude (normalized to a spatial peak value of unity) at the resonator's location. When the frequency of the pressure wave matches the tuned natural frequency of the resonator, its conductance reaches a maximum value. If a resonator or an array of resonators is to be used to suppress combustion instabilities through increased

Figure 6 Simple Helmholtz resonator and a quarter-wave resonator tube.

damping of a targeted acoustic mode, each resonator must be: (a) located near a pressure antinode of the mode, (b) sized to provide adequate conductance, and (c) tuned to achieve the closest attainable match with the natural frequency of the mode. Obviously, if the temperature of the gas in the plenum changes under various operating conditions the effective frequency

of these devices will be altered. Further, the proper location of any such resonator is critical.

8 ACTIVE MEANS FOR NOISE CONTROL

Another option to suppress thermoacoustic oscillations is the application of active means,⁴⁴ which use feedback control with or without adaptive features to suppress thermoacoustic instabilities. It is best explained referring to Fig. 7, showing an implementation of the method in a commercially operated gas turbine.

Signals from a transducer that senses pressure fluctuation or heat release in the combustion zone are processed by a controller, amplified, and transmitted as command signals to an actuator that suppresses the self-excitation process. An overview of different sensors applied to active combustion control has been published by Docquier and Candel.⁴⁶ The active measures modulate flows in either the fuel supply system or the air or exhaust gas stream. Modulation of the air or exhaust gas stream is limited to small combustion systems and/or low-pressure systems. Modulation of the fuel flow rate, on the other hand, is advantageous in most combustion systems because of the moderate volume flow rates that must be modulated. In systems such as blast-furnace stoves, where the volume flows of air and fuel are nearly equal, the fuel flow modulation will not hold an advantage.

The modulation of the air, exhaust gas, or fuel flow rate must occur at the frequency of the thermoacoustic instabilities, which can exceed 1000 Hz, posing a performance challenge in the selection of the actuator. Optimization of both the actuator phase and amplitude is key to control performance, as the flow rate oscillation must produce a change in the heat release rate that is exactly opposite to the heat

Figure 7 Active instability control system installed in a commercial gas turbine. (Reprinted Courtesy of Siemens.)

release caused by the self-excitation process. The actuator thus counteracts the combustion oscillations and the resultant pressure oscillations. Recently, adaptive controllers have been developed in which the controller algorithm changes according to excited frequencies and operating conditions.⁴⁷ Still challenging for active control are systems in which the multiple frequencies are excited or in which the frequencies of the excited modes are not constant. In general, the feasibility and efficacy of active noise control methods are inversely proportional to frequency.

Active operation point control, on the other hand, is related to systems that use control strategies in low-frequency range (1 to 100 Hz). Here, the injection of fuel is regulated to maintain certain flame parameters like the equivalence ratio in a prescribed range of values.

9 NOISE CONTROL ENGINEERING SOLUTIONS

All noise control solutions deal with one or a combination of the source, path, or receiver. The general topic of noise control engineering here includes all of the means to attenuate the unwanted noise along the path from the source to the receiver. The preceding sections dealing with changing the time lag of the flame, fuel staging concepts, and resonators all address attenuation at the source of the noise. Any measures undertaken to control the level of the noise at the receiver are dealt with in other chapters of this handbook. Passive attenuation along the path of the noise consists of external controls: mufflers, insulation and lagging, enclosures or burner internal absorption, all of which are also addressed in other sections of this handbook.

Mufflers These include passive absorptive attenuators made up of parallel splitter baffles or reactive-type mufflers. Absorptive baffles or duct wall liners will typically utilize porous acoustically absorbent materials enclosed, as effectively as possible, within blankets or pillows of acoustically porous materials as a means of retaining the absorbent fill over the life of the unit. In small residential or commercial installations, such silencers may involve low flow velocities and only moderate temperatures (a few hundred degrees Celsius). However, large industrial facilities such as gas turbines will involve high-velocity, highly turbulent flow, at temperatures in excess of 600°C, necessitating specialized designs by experienced vendors and fabricators.

For installations using exhaust gas catalysts of any type for the control of air pollutant emissions, it is important to carefully evaluate the use of absorptive muffler silencers upstream of any such catalyst. The gas passages for such catalysts tend to be small enough that there is a potential for clogging of the passages due to out-migration of fine particles from any acoustically absorptive material installed upstream. However well wrapped the absorptive elements are, a certain amount of material loss is inevitable, with a buildup of lintlike material likely at the catalyst. Commercial manufacturers of industrial mufflers have

developed reactive nonabsorptive muffler designs to overcome the problem of catalyst clogging. Resonators in the burner chamber itself are addressed in the preceding section, but other reactive-type resonators may be installed at any point along the exhaust gas stream.

Enclosures The designer must decide whether to apply acoustical enclosures or acoustical barriers to the burner, the furnace, or the boiler unit to which they attach, or to the appropriate auxiliary component. A peculiarity of combustion noise from large units, especially industrial gas turbines, is their capability of generating significant low-frequency sound emissions, associated, for instance, with combustion oscillations, that may be particularly difficult to attenuate. Furthermore, the very nature of gas turbine operations tends to create low-frequency sound energy that is generated neither by nor within the combustor, nor is it due to combustion-driven oscillations, but rather is generated in the turbulent exhaust gas stream itself. The economies of low-frequency noise attenuation seldom favor modifications to the burner or combustion system, despite the sometimes considerable investment in structures and hardware often necessary for the attenuation of low-frequency sound energy.

Various combustion noise reduction strategies are available to the designer, as with other noise control engineering measures. Simply separating the sensitive receivers from the source, or vice versa, is self-evident. Replacement of noisy equipment with more modern, low-noise designs, continually being developed by manufacturers, will often prove to be the most cost-effective solution.

CHAPTER 78

METAL-CUTTING MACHINERY NOISE AND VIBRATION PREDICTION AND CONTROL

Joseph C. S. Lai

Acoustics & Vibration Unit

School of Aerospace, Civil and Mechanical Engineering

University of New South Wales at the Australian Defence Force Academy
Canberra, Australia

1 INTRODUCTION

Many workers all over the world suffer significant hearing loss as well as psychological and physical stress as a result of exposure to high levels of industrial noise. Many industrial processes involve cutting metal products such as sawing, milling, grinding, punching, piercing, and shearing. As a result of operation processes, the noise from metal-cutting machines can be continuous, such as in saws, drills, lathes, and milling machines or impulsive such as in punch presses.

In this chapter, noise sources due to a continuous metal-cutting process and to an impact/shearing process are discussed. The basic theory of acoustic noise emission due to cutting metal products is introduced. Various noise control options (such as damping, sound absorption, barriers, and vibration isolation) for metal-cutting noise are examined using specific examples. Finally, modern numerical methods for prediction of noise and vibration are described.

2 CONTINUOUS METAL-CUTTING PROCESSES

Metal-cutting machines that fall into this category include saws, drills, lathes, and milling machines. Modern lathes and milling machines are generally not considered as occupational noise problems because an operator of these machines is rarely subjected to an overall A-weighted sound pressure level exceeding 85 dB. In particular, for most milling machines, both the cutting tool and the workpiece (product) are completely enclosed for containing liquid coolants and for safety. These enclosures provide substantial noise reduction. In general, the following noise sources can be distinguished: aerodynamic noise, noise due to vibrations of cutting tool, noise due to vibrations of workpiece, noise due to impact/interactions between the cutting tool and the workpiece, and noise due to material fracture. The radiated noise level is highly dependent on the feed rate of the workpiece, the depth of cut, the resonance frequencies of the cutting tool and the workpiece, the geometry of the cutting tool and the workpiece, and the radiation efficiencies at the resonance modes. Noise due to impact and material fracture will be treated in Section 3 on impact cutting processes.

2.1 Aerodynamic Noise Source

Aerodynamic noise in cutting tools is generated due to the vortex shedding off a spinning tool, such as the teeth in a high-speed rotating saw, producing a whistling noise. If the vortex shedding frequency coincides with the blade natural frequency, the noise radiated can be significantly amplified. It has been found by Bies¹ that the radiated noise for an idling circular saw is characterized by dipoles and the radiated sound power, proportional to the tooth area, increases with the rotational speed to a fifth power. Consequently, it is not unusual that the aerodynamic noise radiated from an idling circular saw at high speeds exceeds an A-weighted sound pressure level of 100 dB.² The strong aerodynamic noise source in an idling circular saw has been attributed by Martin and Bies² to the interaction of the vortex shed by an upstream tooth with the leading edge of the following downstream tooth. Hence this noise is dependent on the tooth geometry.

Various control options to minimize the aerodynamic noise (as applied to a circular saw) are available. By reducing the interactions between vortices and teeth using a variable pitch instead of a fixed pitch, a noise reduction of about 20 dB is possible. Saw blades made of high-damping alloys have been used to reduce blade vibrations at resonance and hence the radiated noise. It has been shown that a noise reduction up to between 10 and 20 dB could be achieved over a range of the peripheral velocity from 30 to 60 m/s.³ Generally, applications of damping disks to saw blades might provide noise reduction up to 10 dB.

2.2 Noise due to Structural Vibrations

Noise due to structural vibrations include noise due to vibrations of the cutting tool, to the workpiece, and to the interactions between the two. In terms of reducing the noise due to vibrations of the cutting tool, for example, in the case of a circular saw, the structural resonance frequencies could be shifted away from the vortex shedding frequency by designing blades with different hole patterns, widened gullets and irregular pitch⁴ or novel tooth design.⁵ In terms of reducing the noise due to vibrations of the workpiece, appropriate clamping and application of damping plates to the workpiece has been found to be useful.

The interactions between the cutting tool and the workpiece might cause instability. In most machining operations such as milling and turning, the cutting forces are highly dependent on the geometry of the cutting tool, the workpiece feed rate, the spindle speed, and the depth of cut. Under certain combinations of these parameters, self-excited instability, known as regenerative chatter, occurs.^{6,7} As a result of regenerative chatter, not only is the quality of the surface finish degraded and the wear of the cutting tool accelerated, but the radiated noise could be also significantly increased. Regenerative chatter and hence noise due to the interactions between the cutting tool and the workpiece could be significantly reduced by proper selection of the spindle speed, spindle speed variation, and the geometry of the cutting tool,^{6,7} as well as active control.⁸

Other control options for machining operations include partially enclosing the cutting area, applying sound-absorbing materials to reflective surfaces, and better vibration isolation of the machine structure.

3 IMPACT METAL-CUTTING PROCESSES

Impact cutting operations typically consist of an initial impact where energy is built up until the material is fractured, accompanied by acoustic emission. The noise and vibration may be transmitted via the machinery and/or via the metal stock. In addition, material handling sometimes produce significant impact noise, such as when metal sheet products are stacked or moved on roller conveyors. As some of the available noise control options such as damping, enclosure, cutting tool geometry are, in principle, applicable for both continuous and impact metal-cutting processes, they will be discussed here in greater details using an impact shear cutting machine as an example.

3.1 Theoretical Considerations

In the classic study of Richards et al.⁹ noise sources of some 43 different machines or processes are listed. In most metal-cutting processes such as sawing, planing, stamping, forging, punching, piercing, and shearing, impulsive forces are involved, and numerous studies have been conducted to study noise sources and noise transmission paths for these operations.^{9–17} Generally, the noise arising from these operations include acceleration noise, ringing noise, noise due to fracture of the feedstock material (cutting noise), and other machinery noise.

Acceleration noise⁹ is primarily generated by the impact between the cutting blade and the feedstock and the air around it is compressed due to rapid surface deformations. This noise normally occurs at low frequencies¹⁸ and is usually small compared with the ringing noise caused by flexural vibrations.^{19,20}

Ringing noise is generated from vibrations of the feedstock and machine structure including machine foundations^{9,12} and is usually a significant contributor to the overall noise radiated during metal-cutting operations. The magnitude of the ringing noise is dependent on the radiation efficiency, spatial averaged

mean-squared normal surface vibrational velocity, the surface area, the density of air, and the speed of sound in air.^{9,12}

Noise due to fracture of feedstock material (cutting noise) is dependent on material properties and could be a dominant noise source especially in presses.^{21–24} Other machinery noise in metal-cutting machinery includes exhaust, operations of clutches, fans, and compressors.

According to Richards,¹³ the total energy in an impact cutting process is composed of the work done on the product, the work transferred to the ground or foundation, the energy dissipated as heat through structural damping, and the energy radiated as noise. It has been derived by Richards¹³ using this energy accountancy concept that the equivalent A-weighted continuous noise level L_{Aeq} is related to the time (t) history of the induced force $f(t)$ by

$$L_{Aeq} = 10 \log_{10} \sum |f'(t)|_{\max}^2 + C = L_{f'} + C \quad (1)$$

Here $|f'(t)|_{\max}$ is the amplitude of the local maximum of the first derivative of the induced force, and C is a constant dependent on the physical properties of the machine structure and the feedstock material. Equation (1) has also been derived by Evensen²⁵ using the Helmholtz integral concept. In deriving Eq. (1), it has been assumed that the dominant radiated noise is due to structural vibration; and that the structure is linear and is only excited at the point of cutting with no backlash noises.

There are two significant implications in Eq. (1): (i) if the induced-force time history is known, then the radiated A-weighted sound pressure level can be predicted; and (ii) if the maximum rate of change of the induced force, $[f'(t)]_{\max}$, can be reduced, then L_{Aeq} will be reduced.

Results obtained for a 200-kN punch press,²⁶ a 80-kN punch press,²⁷ and a roll former shear^{28,29} for a range of operating conditions, materials, material thickness, and tooling parameters (such as clearance and blade profile) support the linear relationship between L_{Aeq} and $L_{f'}$ as given in Eq. (1), but the slope m as indicated in Eq. (2) may not be 1. It has been shown numerically^{28,29} that this might be attributed to the creation of different force sources (backlash forces produced at bearing impacts) at different locations of the machine structure with different magnitudes and phases.

$$L_{Aeq} = mL_{f'} + C \quad (2)$$

3.2 Noise Control Methods

To illustrate the effectiveness of various noise control methods in treating different noise sources, a roll former machine commonly used in sheet metal industries is used as an example here. As shown in Fig. 1a, the flat sheet metal is first uncoiled and passed through a series of rollers to form the finished product profile (Fig. 1b), which is then cut to length in a continuous process using a shear moving with the product.

Figure 1 (a) Schematic diagram of a typical roll-forming production line. (b) Sheet product with a sinusoidal profile. (Reprinted from Ref. 35, with permission of Elsevier.)

The profiled sheet then has to be removed either by an operator or an automatic stacker from the production line and stacked on a pile ready for delivery. These sheet metal products, which come in a variety of profiles, thicknesses and surface coating, are used extensively for roofing, walling, and fencing of industrial and domestic buildings. The lower and the upper blades of the shear are profiled to approximately match the profile of the product. The lower blade is fixed and the upper blade is moved vertically by a driver actuated either mechanically, pneumatically, or hydraulically. The noise radiated at various stages of the operation of a roll former production line can be identified from the noise signature shown in Fig. 2. These include the noise due to roll forming a flat metal sheet into a profiled sheet, cutting the sheet to required length, removing the sheet from the production line and dropping the sheet onto a stack. It can be seen that high impulsive noise levels are produced by the cutting action (fracturing the metal) and the resulting impact-induced vibration of the product and the surrounding structure ("ringing" noise). The noise due to removal of the product from the production line and stacking the product may be reduced by changing the operator's work practice or by installing an automatic stacking machine.³⁰

3.2.1 Control at the Source by Changing Tooling Parameters With the somewhat rare exception of noisy auxiliary equipment, the primary noise excitation in a metal-cutting machine is usually the initial contact between the cutting tool (blade)

and the metal feedstock. Hence, it is important to consider tooling parameters such as blade profile, clearance, and operating speeds to minimize the impact-induced vibrations without compromising the quality of the product. If the initial impact by the blade on the product is reduced, then the ringing noise due to vibration of the product and the machine structure may also be reduced. Considerable research has been carried out into the effects of tooling parameters on radiated noise from punching or piercing machines. It has been shown by Sahlin,²⁴ Koss,^{21,22} and Shinaishin³¹ that the major noise source during blanking is fracture of the work material. Shinaishin's experiments achieved a reduction of 12 dB in radiated noise by applying shear to the punch. Burrows²⁶ and Evensen²⁵ have experimentally investigated tooling effects such as blade clearances and shearing effect on the radiated noise of a punch press and have achieved a reduction of an overall A-weighted sound pressure level up to 10 dB for specific operations.

The linear relationship between L_{Aeq} and $L_{f'}$ suggests that the radiated noise could be reduced by reducing the magnitude of $L_{f'}$ (i.e., the maximum rate of change of the induced force) or the constant term C in Eq. (2). For a given machine, C is determined by physical factors such as the structural response, bulkiness, radiation efficiency, and structural loss factors. $L_{f'}$ may be reduced by changing the tooling parameters such as the cutting speed, clearance, and the blade angle. For the roll former shear, it has been found^{28,29,32} that increasing the blade angle, decreasing

Figure 2 Typical sound pressure trace during the operation of a roll former shear.

the clearance, and decreasing the cutting speed reduces $L_{f'}$. By designing a shear such that the fracturing process is prolonged, $[f'(t)]_{\max}$ may be significantly reduced. This can be achieved by installing the upper blade at an angle to the lower blade as shown in Fig. 3 to allow progressive shearing across the sheet. By increasing the blade angle (i.e., softening the cutting process), the slope of the induced force term in Eq. (2) is reduced. As shown in Fig. 4, a reduction of 22 dB in the maximum A-weighted sound pressure level ($L_{A\max}$) was obtained by increasing the blade angle from 0° to 4° in cutting zinc/aluminum alloy coated steel sheets with an approximately sinusoidal profile as in Fig. 1b. For comparisons, results documented by Bahrami²⁹ indicate a noise reduction of 2 to 5 dB by reducing the clearance and the cutting speed. For all blade angles tested except 0° , Fig. 4 shows that $L_{A\max}$ is significantly increased by even a small misalignment of 3 mm along the blade direction. However, for 0° blade angle, there is a reduction of 10 dB in $L_{A\max}$ because as a result of the small misalignment, not all the points on the blade are in contact with the sheet simultaneously during the shearing operation so that the rate of change of the induced force is reduced. Hence, a new blade set was designed with a constant blade angle of 2° , which corresponds to the maximum stroke of the existing machine. The original blade set consists of an upper blade with a stretched profile and pivoted so that the blade angle varies roughly from 0° to 3° along the blade.³² As shown in Fig. 5, a reduction of 6 dB in over 3 s has been achieved with this new set of blades cutting

850 mm \times 4000 mm \times 0.45 mm profiled steel sheets in an industrial operating environment compared with the old blade. This result indicates that a profile blade with a constant angle is more effective in reducing the shear cutting noise than a profiled blade with varying blade angle along the blade. This is because if the shearing angle changes during the cutting process, the impact due to the blade movement would cause a greater shock in the product and the shear structure and consequently higher noise level. A constant shearing angle during cutting, as implemented in the new blade not only would reduce the cutting force but also would reduce the maximum rate of change of the induced force, hence lowering noise level according to Eq. (2).

3.2.2 Control of the Noise Transmission Path

Treatment of Airborne Noise The purpose of a noise abatement enclosure is to reduce the noise level outside the enclosure by containing and absorbing noise radiated from the enclosed noise source through airborne paths. The magnitude of the noise reduction depends on a number of factors such as the mechanical properties of the enclosure walls, the vibration isolation of the noise source from the outside of the enclosure, and the size of openings or gaps in the enclosure walls. Practical aspects for the design of enclosures have been given by Crocker and Kessler.³³ The basic construction of noise enclosure wall panels normally consists of two components: a noise barrier to provide resistance to transmission of sound and an absorptive inner lining to reduce reflection of sound within the enclosure. It is normally

Figure 3 Sinusoidal blade assembly. (Reprinted from Ref. 32, with permission of Elsevier.)

Figure 4 Effect of shearing blade angle and its misalignment on radiated noise in profiled blade sets. (Reprinted from Ref. 32, with permission of Elsevier.)

necessary to provide doors, windows, ventilation, and other openings. However, a plain opening, which covers 1% of the area of the panel, will reduce the transmission loss to approximately 20 dB.³⁴ It is, therefore, important that when openings cannot be avoided, they should, where possible, open through a long, narrow duct lined with absorptive material.

It is both costly and impractical to enclose the whole roll-forming production line. This is because the production line is often longer than 20 m, the operator requires access to the machine to remove and stack the product once it is cut, and there are a number of points in the process that require continuous observation and frequent operator intervention.

Three different enclosures were designed and tested, details of which are given in Ref. 35. The walls of the enclosure consist of at least two layers of noise barrier materials (such as steel, particleboard, hardboard) and one or two layers of absorption materials (such as rock wool or fiberglass). The sheet

Figure 5 Comparison of the sound pressure level during cutting with an old blade and a new blade. (Reprinted from Ref. 32, with permission of Elsevier.)

product is fed through an inlet opening approximately 100 mm × 1000 mm and a similar sized opening at the exit, as shown in Fig. 1a. The estimated reduction provided by the three enclosures A, B, and C in Fig. 6 against airborne noise is 12, 17, and 19 dB, respectively, which agree well with measurements using an airborne noise source.³⁵ It should be noted that the shears enclosed by the three enclosures had different actuating mechanisms. For the shear with enclosure A, it was operated pneumatically. The shear with enclosure B was operated mechanically using a flywheel while the shear with enclosure C was operated hydraulically.

Typical noise traces from each noise enclosure at the operator's position are given in Fig. 6. The time period indicated by the shaded area in Fig. 6 represents the noise due to cutting. By calculating the equivalent continuous sound pressure level (L_{eq}) for the cutting period from 10 tests, it has been found that the noise reduction provided by the enclosures at the operator's position appears to be limited to 4 to 5 dB, independent of the variety of enclosure construction and shear configurations. As this reduction is substantially lower than the minimum of 12 dB estimated for enclosure A, some noise must be escaping from the enclosures through some structure-borne paths. Thus if only the shear is enclosed, the performance of an enclosure is virtually independent of the enclosure panel design. It is clear that unless the structure-borne noise is reduced, the use of expensive materials and complex construction will not give a corresponding increase in the performance of the noise enclosure.

Treatment of Structure-Borne Noise The enclosures are effective in reducing the direct airborne noise resulting from the blade impacting the product, but

Figure 6 Comparison of A-weighted sound pressure level at the operator's position with and without enclosures: (a) enclosure A, (b) enclosure B, and (c) enclosure C. (Reprinted from Ref. 35, with permission of Elsevier.)

the resulting ringing noise caused by the sheet vibrations due to the blade impact is only slightly reduced because most of the product surface is outside the noise enclosure. To reduce the vibrations transmitted to the sheet from the impact of the shear blades during the cutting action, a damping system was designed to clamp the sheet prior to and just after the cutting of the sheet.

As shown in Fig. 7, the polyurethane dampers were manufactured from a number of damper segments each consisting of a single corrugation. The angle bracket for the upper inlet side damper was fixed in place and the clamping action was achieved by using a large foam rubber spring. The angle bracket for the upper exit side damper was fixed in place, and the damping segments were individually spaced to match the rake of the upper blade. The lower exit side damper was placed on a sprung base with small guiding pins sliding into the lower blade bolster. Where foam springs were used, the foam rubber was glued to the metal base plates and the polyurethane dampers were glued to the

foam rubber using a two-part epoxy glue. The hardness was set to 40 durometer hardness as this was found to be more effective than the harder material. Figure 8 shows that a noise reduction of over 5 dB has been achieved by the sheet dampers at the operator position. The performance cost of the three enclosures ranges from US\$2000/ dB to US\$3500/ dB compared with US\$500/ dB for sheet dampers.

Another Example of Noise Control of Metal-Cutting Machine

Another example of a metal-cutting machine is a 120-tonne expanded-metal press.³⁶ Expanded-metal mesh such as that shown in Fig. 9 is manufactured from flat metal plate feedstock in a range of thickness, sizes, styles, and materials. They are used in a wide variety of applications such as sun screens, machinery safety guards, facades, fences, security door grilles, and floors. Similar to the roll-former shear, treatment of the noise source could be applied by changing tooling parameters such as blade profile, clearance, and operating speed. It has been found that when the operating speed was reduced by

Figure 7 Schematic diagram of sheet dampers.

Figure 8 Comparison of the sound pressure level during cutting with and without sheet dampers.

45%, L_{Aeq} was reduced by 6 dB.¹⁰ To treat the airborne transmission path, a partial enclosure was built around the entry and exit sides of the press. A full enclosure was not practical because of the large size of the press and the need to allow the feedstock to enter and the product to leave from the machine. A noise reduction of between 2 and 7 dB was achieved by this partial enclosure depending on the measurement locations and the length of the unprocessed feedstock plate.³⁷ The feedstock plate on the entry side of the press is the source of structure-borne noise and its vibrations could be reduced by applying mechanical and electromagnetic clamps to the feedstock as shown in Fig. 10. A noise reduction of up to 11 dB was achieved.³⁸

4 NOISE AND VIBRATION PREDICTION

There have been numerous studies into the prediction of metal-cutting machinery noise.^{9-17,39} Equation (2) is one means of estimating the noise radiation for

noise due to impact if the induced-force time history is known. Modern techniques of noise prediction generally employ finite element/boundary element modeling.^{28,39,40} An interesting technique for reducing experimental measurements over a wide range of operating conditions is to use dimensional analysis traditionally employed in the field of fluid mechanics.⁴¹ In the study of the expanded-metal press, it was postulated that the sound pressure p is a function of the feedstock thickness h , feedstock length a , feedstock bending stiffness D , the feedstock density ρ , and press speed expressed in strokes per second (sps). By using the Buckingham π theorem,⁴¹ three nondimensional groups have been found: h/a , $p/(h^2 \times \text{sps}^2 \times \rho)$, and ph^3/D .^{10,42} Data^{10,42} obtained for five different press operating speeds and three different feedstock thicknesses of mild steel indicate that these data collapse onto a single line on a log-log plot with the independent variables being two nondimensional groups: $p/(h^2 \times \text{sps}^2 \times \rho)$ and $(h/a)^{[1.36+0.102(h/h_{ref})]}$. This relationship allows the radiated noise level from the expanded-metal press to be estimated to within 2 dB.

5 SUMMARY

In this chapter, major noise sources in metal-cutting machinery that involve both continuous and impulsive cutting forces have been described. Broadly, they can be classified as aerodynamic noise, noise due to vibrations of the cutting tool, noise due to vibrations of the workpiece, and noise due to the interactions and/or impact between the cutting tool and the workpiece, and noise due to material fracture. These noise sources have been discussed with reference to metal-cutting machines, such as saws, lathes, milling machines, and impact cutting machines. Noise control strategies by treating the noise source, the noise transmission paths for both airborne noise and structure-borne noise have been demonstrated for these machines. These noise control options include the application of damping,

Figure 9 An expanded metal mesh.

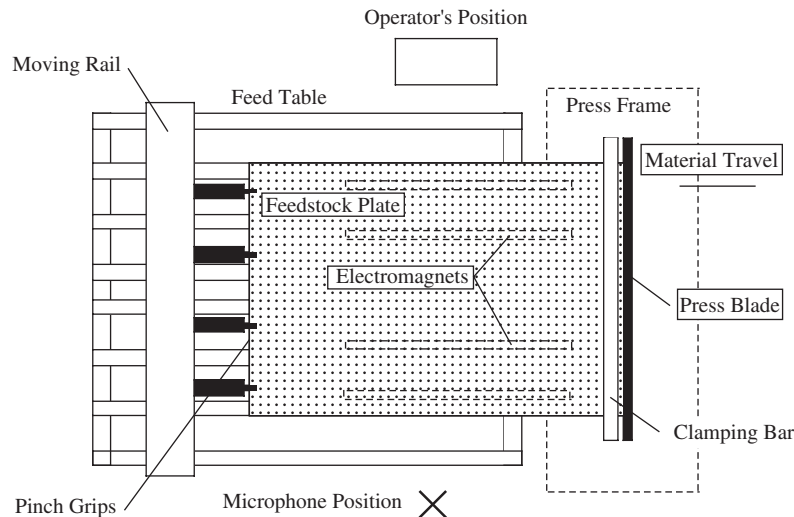

Figure 10 Application of mechanical and electromagnetic clamps to reduce feedstock noise radiation.

installation of enclosures, and the change of tooling parameters such as tool geometry, clearance, feed rate, and depth of cut. In general, an effective noise control strategy would normally involve a combination of all these methods.

CHAPTER 79

WOODWORKING MACHINERY NOISE

Knud Skovgaard Nielsen

1 INTRODUCTION

Woodworking machinery, in the broad sense, includes a wide range of equipment, ranging from off-road equipment used to harvest and transport logs to simple jig saws used in home hobby shops. In the United States, woodworking factories have typically been among the most frequently cited industrial operations by the Occupational Safety and Health Administration (OSHA) for excessive employee exposure to noise. This is due in part to the extremely high noise levels produced by these machines during both operating and machine idle conditions, as well as the relative lack of automation in many segments of the woodworking industry.

Noise produced by woodworking-related machinery results from a variety of general noise sources (motors, gears, hydraulic systems, conveyors, etc.), in addition to noise produced by sources that are unique to woodworking. In some cases, unique solutions need to be sought for noise problems that occur in industrial woodworking operations such as sawmills, planer mills, molding plants, window/door plants, furniture and cabinet plants, wood flooring manufacturing plants, and the like. Many industrial woodworking machinery noise sources result from the use of cutters and saw blades. Although a variety of other sources are associated with the machines that utilize these tools, many woodworking machinery noise problems can be resolved by dealing with the noise produced as a result of the use of cutters and saw blades.

2 NOISE PRODUCED BY MACHINES UTILIZING CUTTERS

Cutters are used throughout the woodworking industry on machines such as planers, molders, panel machines with cutters, routers, and the like to smooth and shape wood products. A typical industrial machine utilizing cutters incorporates feed rolls and holddown bars to transport the workpiece by the cutter (in some cases the cutter is moved by the workpiece). The typical cutter has several rows of knives that protrude above the cutter body (which is typically cylindrical). The machining process is typically a peripheral milling process in which each knife removes a "chip," leaving a relatively smooth surface (depending on the machine feeds and speeds). Traditionally, cutters have incorporated straight

Figure 1 Cutting area of typical industrial moulder machine.

Figure 2 Typical straight knife cutter mounted on moulder spindle.

knives (aligned parallel to the cutter rotational axis), primarily due to ease of manufacture and maintenance (sharpening) issues. This design is quite effective in removing wood material, however, it is inherently noisy. A typical industrial molder and standard straight knife cutter mounted on the molder spindle are shown in Fig. 1 and 2.

Figure 3 Typical planer cross section showing cutter, hold-down bars, feed rolls, and workpiece.

Figure 4 Illustration of straight knife cutter located near stationary surface (table).

2.1 Noise Generation Mechanisms for Machines Utilizing Cutters

A cross section of a typical industrial planer (surfer) is shown in Fig. 3. During idle (when the machine is not cutting wood), the rotating cutter “disturbs” the surrounding air and, for straight knife designs, actually entrains air in the gullet (chip clearance) area similar to the action of a centrifugal fan. Cutters rotating in open space produce turbulence-type noise that is usually broadband in nature (similar to air-handling noise in duct systems). Cutters used in woodworking, however, usually operate in close proximity to the workpiece and stationary surfaces (tables, pressure bars, etc.) used to hold and stabilize the workpiece (as shown in Fig. 3).

The air compression caused by cutter rotation near a stationary surface results in a siren-type noise mechanism, which is an extremely efficient mechanism for sound radiation. This noise is pure tone in nature, dominated by noise occurring at the knife passage frequency [number of knives (n) \times revolutions per minute (rpm)/60 Hz]. The rotating cutter noise increases with rpm and is strongly dependent on the clearances between the cutter knives and the stationary surfaces, as shown in Fig. 4, and increases in the range of 12 dB to 16 dB for a doubling of rpm.¹ The noise level produced by rotating cutters during idle also increases with increasing cutter length at approximately 3 dB per doubling of head length. The increase in noise level with decreasing distance (clearance) between the

Figure 5 Effect of cutter-stationary surface (lip) clearance on idling noise for typical straight knife cutter.

knives and stationary surfaces (table, lip, etc.) is shown in Fig. 5.

The noise during idle for machines equipped with cutters also increases with increased height of the knives above the cutter body and increased open area of the gullet. Figure 6 shows the gullet area for two cutters—one with a closed gullet area (*a*) and the other with a more open gullet area (*b*).^{2,3}

During cutting, an additional noise source usually becomes the dominant source.^{4,5} This noise source is the vibration of the wood workpiece (board), which is excited to vibrate by the periodic impact of the cutter knives (occurring at the knife passage frequency). These impacts cause a structural vibration response of the workpiece primarily at the knife passage frequency and multiples (harmonics) of this frequency. Due to the relatively large amount of damping

Figure 6 Illustration of (a) open and (b) closed gullet areas.^{2,3}

present in wood materials, noise produced by resonant vibration response of the workpiece is not usually an issue. The amplitude of the resulting vibration (and noise) depends on several factors, including (a) the magnitude of the impact force (governed by knife sharpness, cutter rpm, wood properties, hardness, damping, etc.), (b) the workpiece geometry, which governs the efficiency of sound radiation, (c) the cutter design and operating conditions, which governs the vibration excitation response characteristics and frequencies, and (d) the details of the workpiece support/holddown system, which governs the propagation of vibration along the workpiece length, the vibration mode shapes, external damping, and the like.

One of the more important determinants with regard to noise generation during cutting is the workpiece geometry. The workpiece width is strongly related to cutter power consumption (energy input) and also governs the radiation efficiency of the workpiece (narrow workpieces do not radiate low to midrange frequencies as efficiently as wider workpieces). The increase in noise level with workpiece width has been shown to be approximately 6 dB per doubling of width for straight knife-type cutters. The workpiece thickness also affects the vibration response of the workpiece and is responsible for the considerable reduction of noise generation as workpiece thickness increases (beyond about 50 mm thickness). The effect of workpiece length on employee exposure is somewhat more complicated since the vibrational energy provided by cutter impacts is distributed along the workpiece length. Although the total sound power produced by workpieces of different length is nearly constant, localized noise levels (at operator locations) may be substantially different for different workpiece lengths.⁶ Unless vibration suppression techniques⁶ (pressure bars, rubber tire feed rolls, etc.) capable of reducing the propagation of vibration are employed, this vibration occurs over the entire length of the workpiece while it is engaged in the cutter. This has important implications with regard to the use of acoustical enclosures for noise reduction for machines equipped with cutters processing relatively long workpieces; since the length of any enclosure (and/or acoustical tunneling system) must be nearly twice the length of the workpiece to contain the entire noise source within the enclosure at all times.

2.2 Noise Reduction Techniques for Machines Utilizing Cutters

2.2.1 Noise Control at the Source for Machines Utilizing Cutters The most direct approach to noise reduction for machines employing cutters is cutter redesign. A large variety of cutter designs is available, however, the acoustical performance (as well as operational and maintenance characteristics) varies considerably. It is important to consider the overall capabilities of a cutter when selecting alternative designs, including allowable feed rates and depths of cut, power consumption, surface quality, tool wear/breakage, and maintenance. From an acoustical standpoint, a continuous (tightly wound) helical design

Figure 7 (a) Standard straight knife, (b) stagger tooth, and (c) helical cutters commonly used on industrial planers and moulders. (Courtesy of Weinig Group; www.weinigusa.com.)

Figure 8 Smoothing of force–time history for helical vs. straight knife cutter.⁵

(with as many rows of knives as practical) has been shown to be the most effective for reducing both idling and cutting noise.⁵ During idle, the helical design does not compress air as each knife passes by a stationary surface, and instead moves air in an axial direction. During cutting, the combination of a tightly wound helical knife geometry and a relatively large number of knife rows provides nearly continuous contact between the knives and the workpiece, which effectively smooths out the force input that drastically reduces workpiece vibration. Typical straight knife, stagger tooth, and helical-type cutters are shown in Fig. 7. Stagger tooth cutters are widely used in woodworking applications. Although these cutters provide less noise reduction than the true helical design, they typically have maintenance-related advantages. When using helical or shear cutters, it is important to ensure that the axial forces push the workpiece toward the machine guide.

The cutter geometry controls the nature of the vibration excitation of the workpiece, which is directly related to the noise generated. Figure 8 illustrates the cutter force–time history for straight knife and helical cutters.

Figure 9 Effect of workpiece width (w) on cutting noise caused by workpiece vibration for helical vs. straight knife cutter.⁵

The width of the workpiece is one of the primary workpiece-related determinants of the resulting noise levels. The effect of workpiece width on noise level close to the operator location (1 m) for a typical planer/surfacers is shown in Fig. 9.⁵

In some cases noise reduction during idle alone is sufficient to reduce operator exposure to acceptable levels (without dealing with cutting noise). Reductions in idling noise can be accomplished by increasing the knife tip/stationary surface clearance (as shown in Fig. 5), reducing the knife tip projection and open gullet area (as shown in Fig. 6), and altering the geometry of stationary surfaces close to the cutter⁷; such as slotted tables and air guides (shown in Figs. 10 and 11), which help reduce air compression as the cutter knife rotates. These techniques are capable of reducing idling noise levels for machines equipped with cutters by as much as 6 dB, depending on tip speed and stationary surface location.

Machine design changes can also significantly reduce noise. Although most planers, molders, and the like are designed so that cutters operate at fixed peripheral speed, a reduction in peripheral speed of the cutter, when practical, can result in significant reductions in

Figure 10 Slotted table for reducing idling noise on cutter equipped machines.⁷

Figure 11 Slotted table with airflow guides for reducing idling noise on cutter-equipped machines.⁷

both idle and cutting noise. In some instances, a large-diameter cutter operating at a lower rpm (as opposed to a smaller diameter cutter with the same number of knife rows) can also provide a significant noise reduction due to the lower frequency knife impact and the resulting reduction in sound generation efficiency of the workpiece (in this case, the feed per tooth of the milling process would be increased).

Modification of feed rates and rpm are practical noise control alternatives for some machines, such as industrial router machines. These machines range in size from small machines, such as simple pin routers, to large CNC machines that have multiple tables and spindles. The large CNC machines often utilize router cutters (bits) to cut parts from sheet material. The noise levels produced by these operations can be quite high, however, the primary noise source in many cases is vibration of the tool, chuck, and/or spindle rotor system, as opposed to workpiece vibration. For high-speed machines cutting hard materials, the cutting action can excite resonant tool vibration that can produce an intense whistling noise. This resonant noise is quite sensitive to the operational feeds and speeds (which controls the tooth passage frequency) and the tool geometry and chucking details (which controls the resonant frequencies and overall system damping). Noise reduction in these cases can often be accomplished through adjustments in feed rate and or spindle rpm, changes in tool diameter, and/or number of teeth and alternative tool chucking systems that introduce damping at the tool-chuck interface. In cases where vibration of the spindle bearing system is the dominant noise source, it is common for noise levels to be high during idle and actually be lower during cutting due to the damping provided by the workpiece. Noise reduction in this case may require rework of the spindle/bearing system and/or improved balancing procedures.

Machine design changes involving the nature of contact between the cutter and workpiece and the support of the workpiece can also reduce noise. In some cases, it may be possible to convert from perpendicular cutting to parallel cutting by changing from horizontal spindles to vertical spindles [a cutter impacting the workpiece in the weak (perpendicular) direction normally produces more noise than for the parallel case]. Figures 12 and 13⁸ show a double-end tenoner

Figure 12 Double-end tenoner machine with horizontal spindles.⁸

Figure 13 Double-end tenoner machine with vertical spindles.⁸

machine in which the cutting action has been converted from perpendicular to parallel to the workpiece by changing from horizontal to vertical spindles. This approach can reduce cutting noise by as much as 10 dB. Adding workpiece supports near the cutter impact area has also been shown to reduce noise. In general, machine design changes such as those described here should be done in cooperation with the machine manufacturer.

2.2.2 Noise Control in the Path for Machines Utilizing Cutters The use of acoustical enclosures is widespread in the woodworking industry. However, due to the radiation of noise from the entire workpiece while it is engaged in the cutter, many enclosures do not actually enclose the main noise source during operation (much of the vibrating workpiece is outside the enclosure at any given time). The performance

of these enclosures can be improved by using special feed roll and holddown designs, however, such modifications are best left to the machine manufacturer. The use of properly designed, removable acoustical tunnels can also be of benefit when used in conjunction with machine enclosures. In addition to the loss in performance due to the exposed vibrating workpiece, excessive and/or unsealed openings also render acoustical enclosures ineffective. The adverse effect of the exposed vibrating workpiece (which occurs when the workpiece is engaged in the cutter) on acoustical performance is shown in Fig. 14. In the case where an enclosure is designed to enclose only the cutter area, the exposed vibrating workpiece is nearly 100% of the length of the workpiece and there is essentially no reduction in the noise produced by the workpiece vibration. An enclosure that encloses 25% of the vibrating workpiece length is capable of producing only a 6-dB reduction in far-field noise, regardless of enclosure wall construction or how well the openings in the walls are sealed.

Safety/acoustical enclosures are often provided by equipment manufacturers. These enclosures are typically close-fitting units that are often attached directly to the machine frame, as shown in Fig. 15.

While these enclosures are excellent safety enclosures, the noise reduction capability during operation

Figure 14 Approximate loss in enclosure effectiveness due to exposed vibrating workpiece.

Figure 15 Safety/acoustical enclosure integrated into machine design. (Courtesy of Weinig Group; www.weinigusa.com.)

is often limited by the relatively short length of the enclosure, which results in exposed vibrating workpiece noise. If these enclosures are not properly isolated from the machine, vibration can also be transmitted into the enclosure, which is, in turn, radiated as sound, further reducing the enclosure effectiveness. Large free-standing enclosures are by far the most effective, however, this type of enclosure is best suited for conveyor-fed machinery. In all cases involving cutters, the length of the workpiece must be taken into consideration in the enclosure design. Free-standing enclosures of proper length, or when used in conjunction with properly designed workpiece tunnels, can reduce operating noise levels near the machine (due to workpiece vibration) by more than 30 dB. For high-speed planers, this results in a reduction in noise level near the machine from the 115-dB range to below 85 dB. Enclosures of this type can be prefabricated metal construction (with sound-absorbing and damping materials) or conventional plywood/studwall construction (double wall with multiple sheets of plywood and appropriate sound-absorbing materials).

3 NOISE PRODUCED BY MACHINES UTILIZING CIRCULAR SAW BLADES

Sawing is one of the most common woodworking operations. The main types of sawing operations are circular sawing and band sawing. Circular and band sawing operations exhibit some similarity in that noise is produced by aerodynamic sources involving the tooth and gullet area of the blade during idle as well as structural vibration noise that is produced by blade and workpiece-related sources. Although large band saws (of the type used in sawmills) can produce intense noise, circular saws are responsible for the great majority of employee overexposures found in the woodworking industry and are the focus of this section. The circular saw blades under consideration here are primarily of the carbide-tipped design operating at relatively high peripheral speed (greater than 50 m/s) and are commonly found on cutoff/trim saws, single- and multiple-blade rip saws, and panel saws. Large-diameter cutoff saw blades found in primary breakdown operations (sawmills), which typically operate at lower peripheral speeds and are often equipped with operator booths, are not considered in this discussion. A typical industrial cutoff saw machine and circular saw blade used in furniture manufacturing are shown in Figs. 16 and 17, respectively.

3.1 Noise Generation Mechanisms for Machines Utilizing Circular Saw Blades

A great deal of effort has gone into research relating to understanding noise generation mechanisms and reducing the noise produced by circular saws.⁹⁻¹⁴ Although this chapter is concerned primarily with techniques for circular saw noise reduction, as opposed to noise source mechanism theory, it is necessary to review some basic noise source theory as it pertains to noise control techniques. Circular sawing noise can be grouped into three distinct source categories. These sources, although inter-related, are generally accepted to be aerodynamically

Figure 16 Typical industrial cutoff saw machine.

Figure 17 Typical saw blade for cutoff saw machine (450-mm diameter).

produced noise, blade vibration produced noise, and workpiece vibration produced noise.

3.1.1 Aerodynamic Noise The research devoted to aerodynamic noise of circular saw blades has largely consisted of studies of airflow disturbances created by rotating rigid disks with various types of openings (gullets) cut into the periphery. It is usually assumed (a) that aerodynamic noise created by a rotating disk is essentially unaffected by any blade vibration that may be present and (b) that aerodynamic noise results primarily from gullets cut into the periphery (since a smooth disk without gullets or teeth creates relatively little aerodynamic noise). Most researchers agree that the aerodynamic source mechanism involves fluctuating forces set up near the blade periphery.

Figure 18 Effect of tip speed and gullet depth (d) on aerodynamic noise generation for circular saw blades.⁹

However, relatively little agreement among researchers has been achieved as to details of how this fluctuating force is created or how details of disk geometry and disk opening (gullet) geometry affect the nature of the noise produced. Based on experimental studies,⁹ the following observations have been made concerning aerodynamic noise.

1. Aerodynamic noise depends strongly on tip speed and exhibits an approximate velocity to the 5.5 to 6.0 power relationship. This results in a 15- to 18-dB increase in aerodynamic noise level per doubling of tip speed, as shown in Fig. 18.
2. Noise levels depend on details of gullet geometry and saw blade plate thickness. The gullet depth also has a direct effect on noise level, as shown in Fig. 18. The effect of gullet width depends on the gullet width to plate thickness ratio, which has been shown to affect both the magnitude and frequency characteristics of aerodynamic noise. The size (area) of open (gullet) area alone is not a reliable predictor of aerodynamic noise; and details of gullet and tooth geometry (that might affect air disturbances in a nonturbulent flow field) do not have a significant effect on aerodynamic turbulence noise levels for the types of blades and tip speeds under consideration.
3. As with many aerodynamic noise sources, the frequency distribution of circular saw blade aerodynamic noise can be broadband or exhibit a relatively narrow-band character, depending on source mechanism details. This has caused a great deal of confusion with respect to source identification since both blade vibration noise and aerodynamic noise (in some cases) can be pure tone in nature.

3.1.2 Blade Vibration Noise Blade vibration noise results from two distinct sources: resonant blade vibration response, which may occur during idle (excited by aerodynamic or other forces) or cutting (excited by tooth impact forces), and forced blade

vibration response, which is caused by tooth impact that occurs only during cutting.

Resonant blade vibration noise has received the most attention and spawned the greatest number of blade design changes. Part of this attention has been due to the blade stability issues associated with resonant vibration, which has a direct affect on blade performance and minimizing saw kerf. The vibration characteristics of circular plates are such that for typical saw blades, many natural (resonant) frequencies are located within the audible frequency range. In addition, thin, center-clamped steel plates have relatively little damping, which results in an ideal situation for resonant structural vibration sound generation. Since the vibration amplitude at resonance is (theoretically) controlled only by damping, the resonant vibration noise produced by circular saw blades can be extremely intense, sometimes resulting in the so-called whistling saw blade.^{12,15} Most researchers agree that resonant blade excitation during idle can be excited by aerodynamic forces acting near the blade periphery (smooth disks rarely exhibit resonant response when idling), however, it has also been reported that this resonant response can be excited in some cases by excessive blade run-out and/or blade unbalance.¹⁶ The mechanism of sound generation for vibrating structures is well known, and the acoustic power radiated depends on the surface area, the magnitude of vibration, and the acoustical efficiency (which depends primarily on frequency and surface area). The damping present in the saw blade and blade support system also dramatically affect the resulting vibration amplitude and resulting noise generation.

The whistling blade represents an extremely interesting and difficult to predict physical phenomenon. A whistling blade during idle produces an intense pure tone noise resulting from blade resonant vibration. The whistling noise may take several seconds to develop (after the blade is up to speed) and may drift in and out of the whistling condition while rotating at constant rpm. The blade often continues to vibrate after rotation has stopped, producing an audible "ringing" sound. The whistling sound, which is pure-tone in nature, is the result of an excitation force (aerodynamic, etc.) providing energy in the frequency range where at least one strong, easily excited, blade resonant frequency exists. In the case of a typical (lightly damped) saw blade, this can result in extremely high level pure tone noise usually occurring at one of the blade resonant frequencies, which is acoustically efficient (usually several thousand hertz). The whistling blade has been the source of much confusion since, by definition, this type of resonant response is unstable and is the result of a delicate "balance" of conditions. The whistling sound may develop for a given blade on a particular machine and not develop for the same blade on an apparently identical machine. Furthermore, the whistling phenomena may or may not develop for the same blade run on the same machine at different times. Modifications to the blade such as retensioning, minor changes in the contact between the support collars and the blade, the introduction of acoustically

reflective surfaces near the blade, and making very minor changes in rpm can cause tremendous changes in the noise level for a whistling blade or result in the complete elimination of whistling. Attempts to quantify noise levels and noise reductions for inherently unstable whistling saw blades have been unsuccessful.

During cutting, blade resonances may also be excited due to tooth impact. Tooth impact excitation produces broadband vibrational energy as well as energy at the tooth passage frequency and harmonics (multiples) of the tooth passage frequency. Resonant response during cutting may involve one or more resonant frequencies. Figure 19¹⁰ shows one of the many natural frequency (resonant) modal patterns (nodal lines are shown in white) for a circular saw blade. Figure 20 shows the typical effect on noise level due to resonant blade vibration provided by conventional saw collars during cutting.

Forced-blade vibration noise is analogous to a loudspeaker (as compared to blade resonant response, which is analogous to a tuning fork). The acoustic output depends primarily on the input excitation (tooth

impact magnitude and frequency), radiating surface geometry and properties (which govern the resulting vibration velocity), and the acoustic coupling between the blade and the surrounding air. The forced vibration occurring at nonresonant frequencies is not as sensitive to damping as is the resonant case. For this reason, techniques that are quite effective in reducing resonant vibration noise may have relatively little effect on forced-blade vibration noise. Forced-blade vibration noise is characterized by strong frequency peaks at the tooth passage frequency and harmonics. For blades having nonstraight tooth designs, such as alternating top bevels on the top face of the teeth, the base frequency becomes the lowest periodic event frequency (the alternate top bevel spectrum also contains energy at one half the tooth passage frequency and harmonics).

3.1.3 Workpiece Vibration Noise This source primarily involves forced vibration of the workpiece. Since wood-based materials usually have relatively high damping, resonant workpiece response is not usually a noise-related issue. The forced workpiece response is typically of concern only for gang ripping applications involving multiple blades. In these cases, the noise generation mechanisms for the workpiece are similar to those discussed for cutters.

3.2 Noise Reduction Techniques for Machines Utilizing Circular Saw Blades

The primary saw-blade-related noise sources for wood-working machinery involve circular saw blades and band saw blades. Since most band saw noise problems involve large machines typically used in sawmilling operations where employee booths and free-standing acoustical enclosures are routinely utilized, the focus here is on circular saw blades.

The avenues available for reducing noise from circular sawing machines fall into two distinct categories: noise control at the source (through blade and blade support system modifications) and path controls, which involves the use of acoustically treated guards, shields, enclosures, and the like.

3.2.1 Noise Control at the Source for Machines Utilizing Circular Saw Blades

Reduction of Aerodynamic Noise at the Source

Aerodynamic noise for circular saw blades is highly dependent on tip speed and gullet depth, as shown in Fig. 18. The effect of reducing tip speed on noise level is approximately 15 dB per halving of tip speed, and the effect of reducing gullet depth is approximately 8 dB per halving of gullet depth. While adjusting these parameters can be extremely useful in reducing noise, the reduction of tip speed and/or gullet depth often necessitates the use of more teeth to avoid excessive feed per tooth conditions and/or overloading of gullets. Aerodynamic noise can also be reduced through careful selection of gullet geometry, as shown in Fig. 21.⁹ This figure shows the importance of the gullet width to plate thickness ratio in aerodynamic noise generation. Noise level reductions of as much as 10 dB can be achieved in some instances by adjusting this ratio. In general, ratios

Figure 19 Resonant vibration modal pattern for a circular saw blade (1004 Hz excitation).¹⁰

Figure 20 Effect of collar diameter on resonant blade noise generation produced by circular saw blades during cutting.¹⁶

Figure 21 Effect of gullet width-to-plate thickness ratio (w/t) on aerodynamic noise level.¹⁰

in the 1.5 to 3.5 range cause intense noise in a narrow frequency band and should be avoided.

Reduction of Blade Vibration Noise at the Source The primary cause of resonant blade response during both idle and cutting is the extremely low damping present in typical saw blades and blade support systems. A number of “low-noise” saw blades are currently on the market; however, these designs are mostly effective in reducing resonant blade vibration noise during idle. These designs include the use of laser cut slots (with and without damping material) and plugs (usually used in conjunction with expansion slots) to introduce damping.^{17,18} Although the laser cut slots and plugged expansion slots cause localized “disruption” of vibrational wave propagation for certain vibrational modes, the primary noise-reducing mechanism is the damping introduced by relative motion (scrubbing), which occurs in laser slots and plugged holes (similar to the friction damping mechanism provided by riveted joints).

The most notable advance in the reduction of circular saw noise for carbide-tipped blades is the laminated blade design,¹⁹ commercialized in the early 1970s. This design utilizes the principle of constrained layer damping by “bonding” two thin plates together to form the body of the blade. This design is by far the most effective means developed to date for introducing sufficient damping into the saw body to significantly reduce both blade resonant vibration during idle and blade vibration noise during cutting. There are, however, some drawbacks to this approach, including more demanding maintenance procedures. An alternative, but usually less effective, means of introducing constrained layer damping involves the use of collars (concave ground plates clamped to the blade), however, the diameter of these collars must be at least 50% of the blade diameter to be effective in resonant blade noise reductions (this depends on the particular blade resonant vibrational mode shapes, which, in turn, depends on blade design and blade internal stresses). Several free layer damping systems are also on the

Figure 22 Techniques for reducing resonant blade vibration noise: (a) blade collars, (b) slot/plugs, and (c) laminated saw body.

market; consisting of a foil tape that is adhered to the blade. These systems are less effective than constrained layer damping systems and are susceptible to damage under some industrial operational conditions.

Figure 22 shows several of the techniques currently in use in industry to reduce resonant blade vibration. While all of these techniques are capable of preventing the whistling situation during idle, only the laminated blade has been found to provide reliable large-scale reduction of resonant blade vibration noise during cutting.

Forced-blade vibration noise is heavily dependent on tip speed, tooth number, tooth width (kerf), tooth cutting angles (clearance, rake, top bevel, etc.), tooth sharpness, and damping (especially when a tooth passage frequency (or harmonic) is closely aligned with a resonant frequency). In general, forced blade vibration noise levels are reduced by reducing tip speed, increasing tooth number, reducing plate thickness (kerf), employing shear cutting angles (alternate top bevel, etc.), and utilizing sharp blades. Aside from the highly effective laminated blade construction discussed above, typical damping treatments usually provide only minor reduction of forced-blade vibration-produced noise.

Noise control through improved blade design (improved gullet geometry and blade damping systems) is in widespread use for cross-cutting operations, and noise level reductions of 5 dB to 10 dB during both idle and cutting are commonplace. These techniques have been less successful for rip sawing applications due to restrictions on gullet geometry and problems involving blade heating due to friction.

Both resonant and forced-blade vibration noise can be reduced by the use of properly designed blade guides. For some sawmill operations, guides utilizing a liquid film between the guide and the rotating blade are often standard machine equipment. Other guide systems are available that incorporate air-bearing systems, magnetic force systems, and the like; however, these systems are application sensitive and are not in widespread use.

Reduction of Forced-Workpiece Vibration Noise at the Source Reduction of forced-workpiece vibration (also caused by tooth impact) is a difficult issue and has received far less attention than blade aerodynamic noise and blade vibration noise. Fortunately, most circular sawing machines used in woodworking employ one or two relatively thin saw blades that do not result in the high-amplitude workpiece vibration (for wood-based products) as is the

Figure 23 Illustration of correct (*upper*) and incorrect (*lower*) saw blade position.^{2,3}

case for cutters. In the case of a relatively wide workpiece acted on by several circular saw blades spaced a relatively small distance apart, the vibration response closely resembles the response that occurs for a cutter contacting the entire width of the workpiece. Unfortunately, there are relatively few practical and effective source controls for workpiece vibration noise, aside from improved workpiece holddown systems, the use of thinner kerf saw blades, and the use of acoustical enclosures covering the vibrating workpiece.

The use of proper cutting practices can also help reduce workpiece vibration and noise. As discussed for cutters, structural vibration is much easier to produce in the weak (perpendicular) plane. Figure 23 shows the correct (*upper*) and incorrect (*lower*) saw blade position relative to the workpiece. In the correct position, more teeth are in contact with the workpiece at any given time than in the incorrect position; and the cutting force is almost parallel to the workpiece.

3.2.2 Noise Control in the Path for Machines Utilizing Circular Saw Blades The use of acoustical enclosures for circular sawing operations is primarily found on conveyor-fed multiblade trim saws and gang rip saws, where minimal operator interaction with the machine is required and a free-standing enclosure can be used. As is the case for cutter-related enclosures, it is important to consider the vibrating workpiece noise source when considering an acoustical enclosure. The adverse effect of an exposed vibrating workpiece and unsealed openings is similar to the case for cutter-related enclosures.

Figure 24 shows a free-standing enclosure for a multiblade trim saw used in sawmill operations. In this case, the saw blades and the entire workpiece are contained within the enclosure, so that all sawing-related noise sources are enclosed. Typical noise level reductions for this application are 10 dB to 15 dB; resulting in noise levels at the operator location in the 85 dB range during both idle and cutting. Enclosure construction of this type can be the

Figure 24 Commercially available trim saw enclosure.

commercially available metal construction as shown in Fig. 24 (with sound-absorbing and damping material) or conventional plywood/studwall construction.

The use of acoustical treatments in guards located near saw blades has received some attention and has been successful in achieving relatively small noise reductions [usually in the 2-dB to 4-dB range] in aerodynamic and resonant blade vibration noise in some applications. These methods are highly dependent on the details of the application and the results are typically unpredictable.

4 AUXILIARY EQUIPMENT

In addition to cutter- and saw blade-related sources, several other noise sources are often found in woodworking operations. The most important source is related to the operation of chip and dust extraction systems.

4.1 Chip and Dust Extraction System Noise

Due to the fact that dust collection systems are in operation almost continuously during the workday, reduction of noise from the chip and dust extraction system should be pursued even if the noise emission is lower than the noise emission from the wood-processing machines. Operators often find the low-frequency noise from chips and dust extraction annoying even when the wood-processing machines determine their daily noise exposure. Noise control alternatives for chip and dust extraction systems include²¹:

- Using well-balanced fans with low-noise emission
- Using extraction hoods and ducts with smooth-walled interiors
- Installing sound-insulating outer walls
- Using a large radius where ductwork bends ($1.5 \times$ diameter or more)
- Minimizing air leakage
- Avoiding abrupt changes of airflow direction
- Avoiding excessively high extraction velocity
- Installing silencers
- Reducing conveying velocity

- Avoiding the squeezing of chips between the interior walls of the extraction system and moving parts

Pneumatic noise sources (air blow-off nozzles, etc.) are often used to assist in chip and dust collection. Reduction of this noise usually involves changes in nozzle design, nozzle orientation, and the use of silencers. These noise control techniques are covered elsewhere in this handbook.

5 FORESTRY MACHINERY

Forestry machinery includes a variety of handheld tools and mobile machines. The special cases of portable handheld machines and mobile wood chippers are addressed below.

5.1 Portable Handheld Machines

Reduction of internal combustion engine noise is an important noise control measure for portable handheld machines since chain saws, trimmers, and brush cutters normally run without sawing or cutting for considerable time periods. Since internal combustion engines emit more noise than electric engines, electrically powered chain saws, trimmers, and the like, should be used wherever possible.

When buying new machines, low-noise machines should be specified. For portable handheld machines, ISO/TR 22520²¹ may be used for comparing the noise emission data for the actual machine with noise emission data collected worldwide for different makes of machines. The noise emission data for chain saws and for trimmers and brush cutters are presented separately in ISO/TR 22520 for three different regions of the world (Europe, United States/Canada, and Australia).

5.2 Mobile Wood Chippers

Mobile wood chippers are commonly used in processing trees, and the noise levels can be as high as 120 dB at the operator's position. The cutting device is usually a flywheel equipped with cutting blades running in the 1000-rpm range. The cutting process is typically performed in two stages, both of which cause sound generation: (a) the primary cut where the cutting blade contacts the free piece of wood and moves it toward a fixed counter knife and (b) the final cut when the workpiece contacts the counter knife.

Experiments²² have shown that a noise level reduction in the range of 10 dB may be achieved by proper adjustment of the position of the counter knife and the in-feed rolls. This essentially combines the double cut into a single cut, which stabilizes the workpiece during the final cut, thereby reducing noise. The noise emission may be further reduced by partial enclosures and absorbing linings in the in-feed area.²³

6 NOISE EMISSION DATA

Noise emission data should be available for use in the buying and selling of woodworking machinery and equipment. Therefore, there is a need for standardized methods for the determination and declaration of such emission data. A number of basic acoustic standards for

determination of sound pressure levels and sound power levels are available. To obtain reproducible test results allowing comparison of noise emission from different makes of a family of machines, the noise emission must be tested using identical operating conditions.

6.1 ISO Standards for Woodworking Machines

International Organization for Standardization (ISO) 7960 (together with international standards describing acoustic measurement procedures and data reporting) prescribes standardized operating conditions for 19 types of woodworking machines that are widely used in the woodworking industry.

ISO 7960 covers airborne noise emitted by machine tools and operating conditions for woodworking machines.

6.2 ISO Standards for Forestry Machinery

ISO 7182 covers noise measurement at the operator's position of airborne noise emitted by chain saws.

ISO 7917 covers noise measurement at the operator's position of airborne noise emitted by brush saws.

ISO 9207 covers noise emission of manually portable chain saws with internal combustion engines and determination of sound power levels (engineering method, grade 2).

ISO 10884 covers manually portable brush cutters and grass trimmers with internal combustion engines and determination of sound power levels (engineering method, grade 2).

ISO DIS 22868 covers portable handheld forestry machines with internal combustion engines and determination of A-weighted sound pressure levels (at the operator's ear) and sound power levels (engineering method, grade 2).

(Revision of ISO 7182:1984, ISO 7917:1987, ISO 9207:1995, and of ISO 10884:1995)

6.3 Comparison of Noise Emission Data for Families of Machine

Comparison of noise emission data for families of machinery has mainly been organized at a national level. For chain saws, trimmers, and brush cutters, noise emission data have been collected worldwide. Noise emission data for Europe, United States/Canada, and Australia can be found in ISO/TR 22520:2005, which covers A-weighted sound pressure levels at the operator's station for portable handheld forestry machines (comparative data, 2002). An ongoing European project is aimed at establishing similar data for sawing machines and planing machines.

7 CONCLUDING REMARKS

A great deal of information and technology is available for the practical reduction of woodworking machinery noise. Unfortunately, as a recent survey in Germany²⁴ illustrated, many effective noise reduction technologies are not gaining widespread acceptance. This illustrates the need for continuing dissemination of knowledge

focusing on low-noise machine designs, tooling, and operating principles.

Many of the difficulties involved in reducing wood-working machinery noise could be overcome through the more widespread use of automation. During the past decade, the application of computer-controlled machines and robots along with the automation of production lines has provided new opportunities for the successful use of noise-reducing enclosures. The implementation of new production technology and automation is expected to continue to contribute to a decreased noise exposure in woodworking industries in the future.

Several websites^{25–28} are included in the references that provide information on low-noise tooling and machining practices for woodworking.

CHAPTER 80

NOISE ABATEMENT OF INDUSTRIAL PRODUCTION EQUIPMENT

Evgeny Rivin
Wayne State University
Detroit, Michigan

1 INTRODUCTION

Maintaining acceptable noise levels inside production areas of manufacturing plants (on the “shop floor”) is important both for productivity and morale of the shop floor employees. With the exception of forging plants in which forging hammers are the dominating source of noise, noise sources in manufacturing plants can be typically classified in order of intensity/annoyance as¹: (1) *compressed air* (leakages, air exhaust, air-blowing nozzles), (2) *in-plant material handling system*, and (3) *production and auxiliary machinery and equipment*. Production machinery and equipment that generate objectionable noise levels include machines that operate with impacts such as forging hammers, cold headers, stamping presses, riveters, jolting tables; some machine tools; and impact-generating assembly stations. Two basic abatement techniques are (1) acoustical enclosures, which are expensive to build and maintain, may reduce efficiency of the enclosed equipment, and are not always feasible, and (2) noise reduction at the source, which is effective but often requires a research and development effort. Research and development in plant noise reduction in the United States has diminished since the 1970s and early 1980s due to a more lax enforcement of noise level regulations. All the sound pressure levels given in this chapter are A-weighted.

2 COMPRESSED AIR SYSTEM

The flow/jet noise generated by a simple nozzle (Fig. 1), is caused by pressure and velocity fluctuations (turbulence) in mixing of the air jet with stationary ambient air, with sound intensity proportional to the eighth power of jet velocity. *Leakages* can generate intense noise levels (up to 105 dB) and economic losses up to \$1000 per leak per year. The preferred abatement method is maintenance.

Treatments of *air exhaust* noise should satisfy two contradictory requirements: noise reduction and low flow resistance (back pressure). These can be simultaneously satisfied by channeling the exhaust air away from the operator(s) position(s) by hoses/ducts. Another widely used technique is exhaust mufflers selected by noise levels, back pressure, size, and cost. Basic types of exhaust mufflers are shown in Fig 1: multiple jet, dividing the airstream into several jets with less turbulence and 5-dB to 10-dB noise reduction; restrictive diffusers, in which air passes through a fiber mesh or through a porous plug, thus reducing the effective jet velocity and providing a more significant noise reduction, up to 20 to 25 dB, but at the price of a two to three times higher back pressure; and air shroud in which mixing with the ambient air is achieved by its “entraining” along the large outside surface, thus providing for ~10-dB noise

Figure 1 Typical in-plant compressed air nozzles.²

level reduction with low back pressure but resulting in a relatively large and expensive device.

Blow-off nozzles are intense noise generators (up to 110 dB) due to the turbulent mixing of the air jet with the ambient air and, additionally, due to impingement of the jet on the solid target. Also, they consume significant amounts of compressed air per the required blowing force (thrust). "Quiet" nozzles combine noise reduction with delivery of the required force. The most effective technique is synchronization of nozzle usage with the actual needs, thus reducing the noise exposure and saving on air consumption. Multijet nozzles deliver the same magnitudes of concentrated thrust versus air consumption as the simple nozzles, but with noise level reductions of 5 dB to 10 dB; air shroud nozzles provide the same total thrust versus air consumption and noise level reductions of 5 dB to 10 dB, while delivering less concentrated thrust (e.g., for cleaning purposes); restrictive diffusers reduce noise levels by 15 to 20 dB but require two to three times greater air consumption.²

3 IN-PLANT MATERIAL HANDLING SYSTEM

It includes chutes, containers, vibratory feeders, towed trailers, and the like, generating up to 100-dB to 110-dB noise levels. A great variety of the devices requires diverse treatments with some generic underlying concepts.¹

Chutes for parts and scrap are the most widely used devices, such as gravity sliding chutes (mostly, impact-generated noise), rolling chutes (part-rolling noise), vibration-assisted chutes (structure ringing noise).

In *gravity sliding chutes* noise (up to 100 to 105 dB) is generated by ringing of the chute itself and of the dropping parts/scrap pieces. Some noise reduction can be achieved by reducing the drop height. Often noise levels radiated from the chute and from the parts/scrap are commensurate, thus a damping treatment of the chute structure without influencing the part noise radiation (a frequently used technique) is effective only for stiff parts. If the part ringing is important (e.g., sheet metal stampings), an A-weighted level reduction of only about 3 dB reduction can be achieved. Abatement of both sources can be achieved by making the impact surface compliant by assembling it from thin narrow steel strips attached to the chute structure using

Figure 2 Low-noise gravity action sliding chute.¹

self-adhesive foam strips (Fig. 2).¹ In this design, the dropping part has an extended contact area with the compliant chute surface and thus prolonged impact duration, which greatly reduces its ringing. Noise level reductions of 15 dB to 25 dB have been recorded.¹

Gravity rolling chutes are used for transporting round parts, for example, wheel rim preforms, between workstations. The overall ringing is excited by part drop impacts, irregularities of the part shape and the chute rolling surface, scratching the chute walls by the "wobbling" rolling parts, and by co-impacting between the parts. Effective antinoise means are, accordingly, wire mesh drop cushions, wire grid protected rubber lining of the rolling surface and of the walls, and rubber flap curtains preventing direct co-impacting between the subsequent rolling parts. Reduction of the equivalent noise level from 107 to 89 dB after these treatments had been recorded.¹

Vibration-assisted chutes are excited by attached pneumatic ball vibrators generating rotating circular vibration vectors. This results in reduction of effective friction between the chute and the sliding part, thus allowing small inclination angles of the chutes. The noise is generated mostly by ringing of the chute structure excited by higher harmonics of the vibratory force, with vibrators oversized due to low efficiency of friction reduction by the rotating vibration vector. The situation can be improved by attaching the vibrator to the chute as shown in Fig. 3a³ by anisotropic elastomeric gaskets. Such installation has a high natural frequency f_c in the compression (high stiffness) direction of the gaskets and a low natural frequency f_s in the shear (low stiffness) direction of the gaskets. Thus, vibrations with the rotational frequency f_r of the vibrator are transmitted to the chute structure without attenuation in the compression direction and with significant attenuation in the shear direction (Fig. 3b). This transforms the circular vibration vector into a narrow elliptical vector, which can be inclined to the chute surface by an appropriate positioning of the bracket. The optimal inclination angle, $\sim 45^\circ$ (which can be adjusted while in place), results in about 10 times reduction of part transporting time along the chute; thus smaller vibrators and/or lower air pressure can be used, with the corresponding noise reduction and significant savings of compressed air. In addition, the elastomeric gaskets provide isolation of the high-frequency vibration harmonics (e.g., the second-harmonic $2f_r$ in Fig. 3b) from the chute structure. A 23-dB noise level reduction (from 106 dB to 83 dB) has been recorded.³

3.1 Containers

Parts/scrap pieces conveyed along the chutes are usually further transported in containers. Parts, especially massive, generate noise levels in excess of 100 dB (ringing part and ringing container structure when the part hits its wall), usually decreasing while the container fills up. Large numbers of containers are used in manufacturing plants, but only a few working stations are associated with the container-generated noise. Accordingly, treating/"quieting" all the containers is useless and very expensive. The potentially

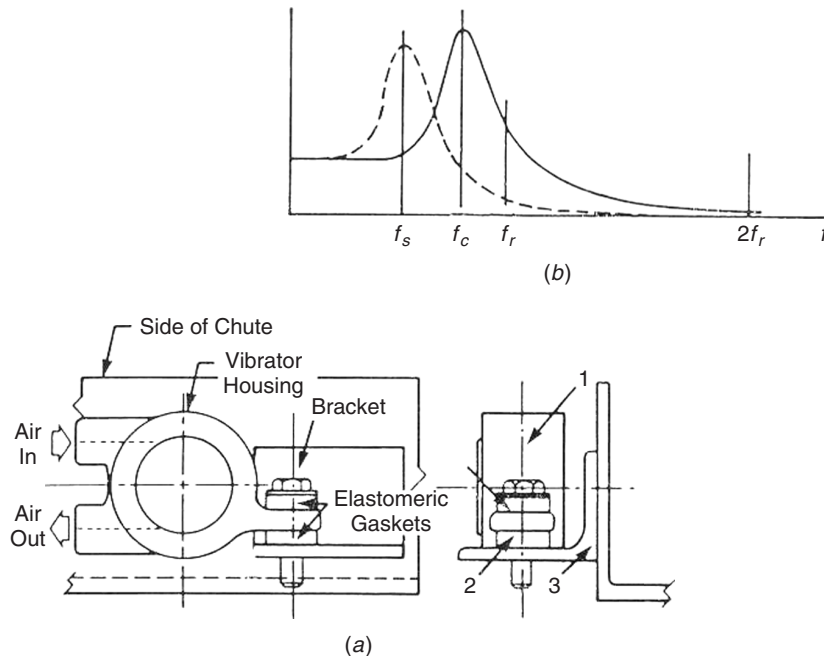

Figure 3 (a) Vibration force vector transformer and (b) its transmissibility plots.³

noisy workstations should be equipped with noise-reducing means not obstructing the operation. Filling an empty container with perishable foam (e.g., soap foam) reduces noise levels by ~ 5 dB. Pressing rubber-coated rollers externally to the container wall results in an A-weighted noise level reduction of about 6 dB.¹ The pressing action is activated by the weight of the container when it is placed into its workstation.

3.2 Towed Trailers

In many plants empty and loaded containers are conveyed by trains of up to five to six towed trailers driven at speeds up to 10 mph (16 km/h). Wheel excitations from floor unevenness induce intense structural vibrations with accelerations exceeding 1 g, causing noise and a secondary rattling of containers. Friction reduction by vibration also causes horizontal movements/impacting of containers. Noise levels up to 115 dB were recorded, together with fast deterioration of bearings, king pins, and other joints caused by dynamic loading. Since loads on trailers vary significantly (empty trailer—trailer loaded with empty containers—trailer loaded with full containers—stationary trailer loaded with stacked-up full containers in storage mode), a spring suspension with linear load-deflection characteristics is either too stiff for lightly loaded condition or has an excessive deflection for the loaded condition, preventing assembling of the train. Also, an expensive redesign of the trailers inventory is required.

Rubber-metal *shear disk* suspension (Fig. 4)¹ having nonlinear hardening characteristic and nearly

constant natural frequency ~ 5 Hz of the trailer regardless of its loading resulted in about 16-dB reduction of equivalent noise levels combined with small (~ 15 mm) height difference between empty and fully loaded trailer, ~ 15 times reduction of impact accelerations and, consequently, 10 times greater periods between repairs. In Fig. 4, axle 2 of wheel 1 is connected to frame 3 via two “shear disks” comprising rubber-in-shear layers 4, 5, 6 sandwiched between metal plates 7, 8, 9, 10. At low trailer loads all rubber layers are deforming (connected in series) thus having low stiffness. At an increased load, the softest rubber disk 4 contacts the axle, and stiffness is increasing; at even greater load, the next rubber disk 5 contacts the axle; and in storage mode all disks contact the axle thus preventing their overstressing.

3.3 Vibratory Feeder Bowls³

These “solid-state” devices are widely used in manufacturing, especially assembly, operations, but high noise levels up to and sometimes exceeding 105 dB prevent even wider use. The principal noise sources are ringing of the bowl in the 250- to 500-Hz range excited by high-frequency harmonics of the driving vibratory torque; ringing in the 2- to 8-kHz range excited by impacts from conveyed parts moving in a “tossed up” regime; and noise radiation in the 2- to 16-kHz range from diffuser-shaped bowl cavity. The corresponding preferred noise abatement techniques can be applied individually or combined.

External damping treatment of the bowl and of the nonworking surfaces of the part track and the exit ramp

Figure 4 Castor wheel with shear disk suspension.¹

achieves ~10-dB reduction. Instead, the bowl can be made from a nonringing plastic (e.g., polyurethane). Coating the working track surface with a high-friction and low-impact velocity restitution coefficient material (e.g., polyurethane) reduces noise by about 8 dB and accelerates uphill vibration-stimulated conveyance, up to 40% for solid parts (less for thin-walled parts). Screening the radiated noise by a “see through, load through, reach through” segmented acoustical cover made from a transparent high-damping polyvinyl chloride (PVC) material (Fig. 5) with segments prevented from sagging by thin spring steel strips provides a noise level reduction up to 12 dB. Combinations of these technique reduce the noise level by 15 dB to 20 dB.

4 PRODUCTION MACHINERY

Both stationary and handheld production machinery becomes a dominating factor in the noise environment after compressed air and material handling systems are treated. Total acoustical enclosures for stationary machinery, in addition to high initial costs, reduce productivity of the machine by 3 to 5%, generate substantial maintenance expenses (up to 15 to 20% of the initial costs annually), create inconveniences for machine operators, and may become a problem for management if enclosures are used by employees as nonacoustical shelters. Two cost-effective noise abatement techniques are selection of best models/units, especially for handheld machines, and engineering treatments based on studies of noise-generating mechanisms.

Figure 5 Segmented acoustical lid for vibratory feeder.³

4.1 Handheld Machines

Since many models of handheld machines for a given purpose are commercially available, selection of the best units can be very effective. Similar machines of different designs may vary substantially in sound pressure level, performance, and energy consumption. Often, a quieter machine has better performance characteristics and/or lower energy consumption, thus making the selection a very cost-effective exercise. This was confirmed by comparative testing of various models of handheld compressed-air-driven grinders, whose noise levels differed within the 12-dB range and air consumption varied within a 2:1 range. Noise levels of different design pile drivers vary by as much as 43 dB.⁴ Selection testing of handheld machines requires low-noise load simulators, for example, eddy-current or magnetic power brakes for machines with rotating tools, and using nonringing workpiece simulators for percussion machines.

In airplane factories, noise from riveting produces short-duration, high-amplitude sounds with high-level components at frequencies where the human ear is most sensitive. Control of the impulsive sound of riveting without affecting production was achieved by applying constrained-layer damping pads to the skin of an aluminum panel being riveted⁵ (treatment similar to silencing treatment of containers described above). A pad is held against a panel by a vacuum pressure of about 90 kPa. The time-averaged A-weighted sound pressure level at a position representative of the ear of the operator of a riveting hammer was reduced by about 5.5 dB.

5 NOISE SOURCES AND THEIR TREATMENT FOR STATIONARY IN-PLANT MACHINERY

The selection process is not always effective for stationary machines since the machine noise is usually

specified at idle condition, without loading by the working process, and a quieter machine at idle is not necessarily the quietest one in production. Stamping press noise level specifications (without a die) call for 84 dB, while the part-producing presses are characterized by averaged (equivalent) noise levels up to 90 dB to 95 dB, with peak levels up to 105 dB to 110 dB. Testing of the machine under load is not a solution since the test results depend on the tool (die) design, workpiece material and design, and the like. Accordingly, it is important to perform testing in a simulated environment wherein unified loading conditions are used for different machine models.

Figure 6 shows a load simulator for punch presses⁶ that is placed on the press bolster instead of the die for noise testing. Disk (Belleville) springs (2) can be preloaded by calibrated or instrumented bolts (1) to the specified load. When the press ram on its way down is touching the head (6), it unloads the bolts (1) from springs-induced load. The ram travel for fully unloading the springs is equal to the small initial deformation of the bolts. Both the load magnitude and duration of the unloading process are adjustable by changing the preload and by changing length and cross section of the bolts (1). Thus, the load pulse applied to the ram and to the press structure is very short, similar to the load pulse during the breakthrough event in the punching operation, and can be adjusted according to the test standard/specification.

5.1 Impact Machinery

The most intensive noise emitters in manufacturing plants are machines generating impact forces for performing productive work. The most numerous impact-generating machines are metal-forming machines, although some other types of machinery (such as jolting tables in foundries) have similar noise-generating mechanisms, which can be treated by the same techniques as metal-forming machines. Metal-forming machines represent the most productive metal-working equipment. Also, in many cases

Figure 6 Punch breakthrough load simulator.⁶

the workpieces produced by these machines are characterized by significantly better material properties. This includes forging machines for complex three-dimensional shaping of material as well as sheet metal stamping (forming and punch) presses, much more numerous than the forging machines. The noisiest group—forging machines—include “drop” or “anvil” and “counterblow” hammers, and “screw” and “crank” forging presses. The noisiest mechanical forging crank presses are embodied as horizontal cold-heading machines. Hydraulic presses are substantially more expensive but less noisy.

5.2 Stamping Presses

Noise sources in *stamping presses* can be distinguished as “idling” sources, such as gear noise, air noise, impacts in clearances of revolute joints and gibbs (guideways), impacts of the stripper plate against the upper die and keepers (Fig. 7), “knock-out bars” in cold-forming presses, and process noise. All impact interactions excite structural modes of the press frame, thus adding ringing of the structure to the impact noise. The process noise in sheet-metal forming presses has a relatively low intensity, mostly due to ringing of the metal sheet during loading into and unloading from the die. On the other hand, the breakthrough event in punching presses is characterized by a short intense force pulse that excites numerous structural modes of the press. A significant reduction of the press noise is possible only by addressing both groups of sources.^{6,7}

Noise of the breakthrough event can be reduced by optimizing velocity of the punch in the moment of impact (by adjusting the die setting), by tuning the clearance between the punch and the die, or by a proper die alignment. Optimization of these parameters can reduce the peak noise level by 5 dB to 10 dB. Shearing/slanting of the die and/or punch staggering extends the duration of the force pulse and has a substantial effect in a broad frequency range. However,

Figure 7 Stamping die system of a punch press.⁶

it increases initial and maintenance (sharpening) die costs. In some cases it can adversely affect the part quality.⁶ Hydraulic shock absorbers⁸ arrest the abrupt load release after the punch breakthrough resulting in 2-dB to 6-dB peak noise level reduction. The absorber has to be readjusted for the die changeover; may require an oil-cooling device; increases press power consumption by 4 to 15%; and is expensive. In the presses driven by servo-controlled motors and ball screws, a controlled change of the breakthrough load pulse may result in 3-dB to 5-dB noise level reduction.⁹

The most important noise sources besides the breakthrough event are hard impacts in auxiliary systems of the presses (stripper, keeper, knock-out bars) and in structural clearances. Since impact-generated contact pressures in these mechanisms are very high (up to ~6 MPa), solid rubber cushioning pads (allowed contact pressure from impact load 0.5 to 1.0 MPa) cannot be used. Thin-layered rubber-metal laminates easily tolerate contact pressures above 50 to 60 MPa^{7,10} and can be used as durable impact cushions. Use of the rubber-metal laminated cushions for the slide-connecting rod ball joints and for keeper joints resulted in an A-weighted sound pressure level reduction of 2 dB to 2.5 dB for each treated joint.⁷ A similar reduction had been achieved by using the stripper plate made from a wear-resistant plastic (UHMW polyethylene) reinforced by a steel frame, instead of the solid steel plate.⁶

The structural ringing can be reduced by using more powerful (overrated) presses to perform relatively low-force stamping operations and by applying damping treatments to the frame. Both approaches are expensive ones for a relatively modest noise reduction (~3 dB). Obviously, the above-listed source treatments also result in a reduction of the structural ringing.

Noise in the vicinity of stamping presses can be significantly reduced by installation of the press on properly selected vibration-isolating mounts. Such installation is especially important if the press is surrounded by an acoustical enclosure. Vibration isolation of a majority of machines in a shop reduces the overall noise level in the shop; see Section 5.4.

5.3 Drop Hammers and Forging Presses

The maximum work capacity for drop hammers is determined by the mass of the dropping ram (tub) and by the height from which it is dropped, and is measured by the maximum energy of one blow W_{\max} in newton-metres or joules, and for presses by the maximum force F_{\max} in newtons. A hammer and a screw press are equivalent as production machines if the W_{\max} of the hammer in newton-metres and F_{\max} of the press in kilonewtons are related as 3.5:1; a hammer and

a crank press are equivalent if $W_{\max}:F_{\max} = 2.5:1$; and the equivalence ratio between the maximum forces of a crank press $F_{\max c}$ and a screw press $F_{\max s}$ is $F_{\max c}:F_{\max s} = 1:0.75$.¹¹ Thus, a crank press with $F_{\max} = 10,000 \text{ kN} = 10 \text{ MN} \approx 1000 \text{ ton}$ is equivalent from the forging point of view to a drop hammer with $W_{\max} = 25,000 \text{ N} \cdot \text{m} = 25 \text{ kJ}$. A crude but useful approximation for "fast" A-weighted sound level of forging machines at 1 m (L_{A1}) and 7 m (L_{A7}) from the machine as a function of the machine capacity are shown in Table 1, where W_{\max} is in kilonewton-metres, and F_{\max} is in meganewtons.

Considering the above equivalencies, drop hammers are exhibiting the highest sound levels and the slowest decay with the distance, followed by screw presses and crank presses. For the latter, the noise levels are only weakly correlated with their size. The "true" peak sound emanated by forging hammers is ~20 dB higher than the "fast" levels listed in Table 1.¹¹

The sound intensity is increasing with each blow until the workpiece (billet) is completely forged, and the most intense sound pulse is generated by die-to-die impact. This most intensive impact is used to describe the noise emission of forging hammers. The major noise-generating mechanisms are¹¹:

- Sudden deceleration of co-impacting bodies (dies) with the radiated pressure pulse depending on strength (magnitude) and duration of the blow pulse (Table 2).¹²
- Transverse expansion of billet and dies during the blow, with the generated sound pressure level depending on the blow intensity, billet/die cross section, and transverse stiffness.
- Structural ringing of the hammer at its natural modes, which intensifies by up to 10 to 15 dB if the blow is off-center.
- Air expulsion from between the dies prior to the impact produces shock waves whose pressure levels depend on impact velocity and die design; not a significant noise source outside of low-frequency range (<100 Hz).
- Vibration of the ground excited by the pulselike blows and contributing to the noise radiation; its

Table 1 Noise Levels of Forging Machines

	Drop Hammer	Screw Press	Crank Press
L_{A1}	$0.10W_{\max} + 112$	$1.1F_{\max} + 99$	107
L_{A7}	$0.10W_{\max} + 106$	$1.1F_{\max} + 92$	99

Source: From Ref. 11.

Source: From Ref. 12.

role in the overall noise level is increasing with increasing distance from the hammer, besides being itself a major vibratory annoyance.

Noise and vibration generated by forging hammers are objectionable both for the operators and for the surrounding communities. The few practical noise abatement techniques addressing both of these constituents are increasing the frame mass of a hammer for a given blow strength (e.g., by using overrated hammers), improving die design to produce a desired workpiece with less intense blows, and introducing controllable hammers allowing fine tuning of the blow strength to the billet size and condition.¹¹

While the hammer operators are somewhat protected by individual ear protectors, the greatest objections to forging hammers' noise and vibration are from residents of the areas surrounding the forging shop and from users of precision and other vibration-sensitive equipment. The noise levels at the "property boundary" of forging shops are 90 to 100 dB,¹¹ far exceeding the norms for residential areas. Ground-transmitted vibration is even more objectionable, especially in winter time in cold areas, when the frozen soil is a much better vibration transmitter. Vibrations from forging hammers may blur microscope images and cause shaking of office equipment at as far as 300 m from the shop, with much worse effects on frosty days. Transmission of noise and vibration outside the shop can be reduced by acoustical treatment of walls (and ceilings) and by vibration isolation of hammers.

Usually hammer is being installed on a massive foundation block supported by compliant steel springs or rubber isolators. The maximum amplitude of force transmitted to the ground $P_{g \max}$ relative to blow force magnitude P_0 (Table 2) is¹²

$$\frac{P_{g \max}}{P_0} \cong 6.9 \sqrt{\frac{m_3 m_4^2}{[(m_3 + m_4)(m_1 + m_2 + m_3)] \times (m_1 + m_2 + m_3 + m_4)}} \tau_{p1} f_{vz} \quad (1)$$

where m_1 is mass of dropping tup + upper die, m_2 = mass of anvil, $m_3 = m'_3 + m''_3$ is mass of frame m'_3 attached to foundation block m''_3 , m_4 = mass of foundation box, τ_{p1} is blow pulse duration (Table 2), f_{vz} is vertical natural frequency of hammer + foundation on vibration isolators.

Equation (1) describes the effectiveness of the vibration isolation system. It shows that for the short pulse excitation the transmitted force ($P_{g \max}$) is proportional to the natural frequency of the isolation system (for isolation of steady, e.g., sinusoidal, vibrations the transmitted force is proportional to the second power of the natural frequency). However, in the latter case the transmitted vibration is of the same frequency as the excitation, while for the pulse excitation a less hazardous low frequency (equal to f_{vz}) is transmitted. The isolation effectiveness does not directly depend on stiffness of the auxiliary isolation system between the anvil and the hammer frame (usually belting, oak boards, etc.).

Damping in isolators improves effectiveness of the isolation system, thus f_{vz} can be increased (thus allowing to use a smaller and less expensive foundation block) by increasing damping (log decrement δ of the isolation system) if the following isolation criterion Φ_{fh} is kept constant,

$$\Phi_{fh} = \frac{f_{vz}}{\delta^{0.25}} \quad (2)$$

Increasing damping in both main and anvil isolators from $\delta = 0.3$ to 1.25 allows to increase the natural frequency of the vibration isolation system by a factor of ~ 1.5 , from $f_{vz} = 2 - 6$ Hz to $f_{vz} = 3 - 9$ Hz without reducing isolation effectiveness.

Other pulse-generating machines are jolting tables in foundries, impact-testing machines, and the like. Usually, these machines are smaller than hammers and require less operator supervision (e.g., automatic cycling) and often are used with rigid or flexible (PVC strips) enclosures. Protection of the surrounding area is provided by vibration isolation conceptually similar to that of forging hammers above.

Hydraulic forging presses and large punch presses generate significantly lower noise levels since the ram motion and, thus, structural vibrations can be controlled by the electrohydraulic system.¹³ While the overall noise levels in the vicinity of a hydraulic forging press are still significant, the main sources of the noise are not necessarily the forging force pulse related, but are due to compressed air systems, material handling systems, and ancillary devices. These sources can be treated by the techniques described above. For example, noise sources for the hydraulic forging press for artillery shells¹⁴ (the overall level 110 dB) are impacts of shells moving along the gravity chute (95 dB), pneumatic controls on shell-handling robotic arms (110 dB), air jets for blowing out the shell (110 dB), and hydraulic pumps and electric motors (85 to 88 dB).

While there are few forging hammers in industry and usually not more than two or three in one plant, cold headers are widely used for making standard fasteners and relatively small mass-produced mechanical parts. Usually dozens of cold headers are placed in one shop resulting in sound pressure levels of 90 dB to 102 dB and sound power of 99 dB to 115 dB.¹⁵ Techniques for noise reduction in the source include reduction of acceleration/deceleration of the ram, damping enhancement of the structure (frame), damping enhancement of the ejection rocker arm and the flywheel, tightening clearances between the crankshaft and the connecting rod to reduce rattling during reversals, and vibration isolation. These techniques are not widely adopted by the machine manufacturers. However, practically all models of cold headers can be supplied with the full enclosures that, if properly maintained, can provide 9- to 13-dB noise level reduction.

Noise radiation from the shop floor as well as disruption of operation of precision production and measuring equipment can be reduced by mounting cold headers on vibration isolators having high vertical

(compression) stiffness and low horizontal stiffness (in the working pulse direction), thus attenuating the pulse transmission to the floor. The recommended horizontal natural frequency for high-force/low-speed machines is $f_x \leq 7$ to 9 Hz. It is desirable to assure decoupling horizontal/rocking and vertical modes in the vibration isolation system¹² to reduce vibration excitation in the vertical direction where the floor stiffness is relatively low.

5.4 Metal-Cutting Machine Tools

Most modern machine tools use coolant fluids at high pressures. Because of this, they usually have hermetic enclosures around the working area, which provide a noise abatement effect. There are sometimes objectionable noise levels from machine tools using milling cutters due to the impact character of cutting. A noticeable noise reduction can be achieved by using milling cutters with nonuniform pitch of their cutting edges, used for reduction of chatter vibrations.¹⁶

The important noise source is radiation from the floor due to high-frequency vibration transmitted from the machine tool. Installation of a majority of machine tools on vibration isolators was shown to result in 2-dB to 3-dB noise level reduction in the shop and noise level reduction in the most annoying frequency range of 2000 Hz to 3000 Hz by 4 dB to 5 dB.¹²

1 INTRODUCTION

A frequent problem in the manufacturing industry today is the vibrations or chatter induced in machine tools during machining; for example, in turning, milling, boring, and grinding. The vibration of machine tools may be divided into three different classes: (1) free or transient vibrations of machine tools excited by other machines or engagement of the cutting tool, (2) forced vibrations usually associated with periodic forces within the machine tool, for example, unbalanced rotating masses, and (3) self-excited chatter that may be explained by a number of mechanisms. These mechanisms include, among others, the regenerative effect, the mode coupling effect, the random excitation of the natural frequencies of the machine tool caused by the plastic deformation of the workpiece material, and/or friction between the tool and the cut material. Vibrations in machine tools affect the result of machining, particularly the surface finish. Furthermore, machine tool life can be correlated with the degree of vibration and acoustic noise introduced. Machine tool chatter may be reduced by selective passive or active modification of the dynamic stiffness of the tooling structure and/or by the control of cutting data to maintain stable cutting. Forced unbalance vibration in rotating tooling structures may be reduced by passive balancing or active online balancing.

2 MACHINE TOOL CHATTER AND VIBRATION

In machine tools the chain—tool, tool holder system, machine structure, and workpiece—forms complicated dynamic systems.^{1–4} The vibration of machine tools may be divided into three different classes: free or transient vibration, forced vibration, and self-excited chatter or vibration.^{1–4} Free or transient vibrations of machine tools may be excited by other machines in the environment via the machine tool base or/and by rapid movements of machine tables, engagement of the cutting tool, and the like. The forced vibrations are usually associated with periodic forces within the machine tool, for example, unbalanced rotating masses, the intermittent tooth pass excitation in milling. This type of vibration may also be excited by other machines in the environment of the machine tool via its base.

Machine tool vibrations during machining operations are usually termed *self-excited chatter* or *tool*

vibration. Depending on the driving force of tool vibration, the vibration is generally divided into one of two categories: regenerative chatter (secondary chatter) and nonregenerative chatter (primary chatter).^{1–3,5–8} Extensive research has been carried out on the mechanisms that control the induction of vibrations in the cutting process. The majority of this research has been carried out on dynamic modeling of cutting dynamics focusing on the analytical or a numerical model. Usually, the purpose of these works is dynamic models that enables to predict cutting data that enables stable cutting and maximize the material removal rate.^{1,2,4,9–11}

2.1 Chatter Mechanisms and Properties

The two most widely used theories explaining self-excited chatter are the regenerative effect and the mode coupling effect. These theories are generally explained based on the dynamic interaction of the cutting process and the machine tool structure, that is, the basic cause of chatter.^{1–3,12} Self-excited chatter and two of its energy-providing mechanisms, the regenerative effect and the mode coupling effect, are usually described as follows: During cutting, a force $F_r(t)$ is generated between the tool and the workpiece; see Fig. 1.

The cutting force will strain the structure elastically and may cause a relative displacement of the tool and

Figure 1 External longitudinal turning.

Figure 2 (a) Simplified block diagram of the closed-loop cutting-process structural system and (b) the principle for cutting tool regenerative chatter.³

the workpiece, which alters the tool and workpiece engagement. This, in turn, indicates a feedback system relation between the cutting force $F_r(t)$ and the relative displacement of the tool and the workpiece; see Fig. 2a. This justifies a possibility for the initial vibration to be self-sustaining (unstable) and increase, with the machine oscillating in one of its natural modes of vibration. Basically, the closed-loop cutting process structural system is considered unstable if a mechanism exists for transferring energy into the structure to maintain vibration.^{1-3,12} The regenerative effect is considered to be the dominant mechanism of instability and chatter.^{1-3,12} It may occur when successive passes of the cutting tool overlap, that is, when the tool at any instant is removing an undulation on the workpiece surface that was cut on the previous pass of the tool or revolution of the workpiece. This is illustrated in Fig. 2b where h_0 is the intended chip thickness, $h(t)$ is the actual chip thickness at time t , $y(t)$ is the displacement of the tool in the y direction at time t , and $y(t - T)$ is the displacement of the tool in the y direction at previous pass of the tool or revolution of the workpiece.

Depending on the phase between these waves on the workpiece surface, the force variation and excitation energy may increase after successive passes of the tool and the vibration will build up.^{1-4,12} The limit of stability as a function of frequency—a stability chart—may be produced from

$$1 = -G_{yr}(f)[k_1(1 - \mu_c e^{-j2\pi f T}) + k_2 2\pi / \Omega j 2\pi f]$$

where $G_{yr}(f)$ is the cross receptance between the cutting force $F_r(t)$ and the tool response $y(t)$ (m/N), k_1 is the cutting stiffness coefficient (N/m), μ_c is the overlap factor, k_2 is a constant (N/m), Ω is turning the rotational speed of the workpiece (rad/s), and f is frequency (Hz).³

On the other hand, the mode coupling effect may occur when successive passes of the tool do not overlap and when the eigenmodes of the machine-tool system are closely matched. The mode coupling chatter exists if vibration in the primary cutting direction generates vibration in the feed direction and vice versa. This results in an elliptic tool tip motion in the primary direction-feed direction plane, where the part of the elliptic motion in direction of the primary direction produces a greater average depth of cut as compared to the part of the elliptic motion where the tool tip has a motion in the reverse primary direction. This results in a net input of energy to the machine-tool system.^{1-3,12}

The mode coupling effect is in the set of primary chatter mechanisms. The set of primary chatter mechanisms also includes random excitation of the machine tools eigenfrequencies due to plastic deformation of workpiece material and/or friction between the tool and the cut material, the tendency of the cutting force excitation to change with the cutting speed, the dynamic effects of the geometry of the cutting tool on the cutting process, and so forth.^{1,10,11,13,14}

In this context it should, however, be observed that machine-tool chatter frequently exhibits stochastic properties.¹⁰⁻¹⁴ This may be explained by the fact that the mechanical properties of materials, such as chemical composition, inhomogeneity, microstructure, and hardening, generally have spatial stochastic variations.¹⁵ As a consequence of the stochastic variation of the mechanical properties, the deformation properties of the material will also show random variations.¹³ In Fig. 3 photos of the material structure of two different work materials, one cast iron and one stainless steel, are shown.

This in turn will introduce a broadband excitation of the machine tool.^{10,11,13} Generally, machine-tool systems are classified as narrow-band systems.^{4,10,11,13,16,17} The chatter or tool vibration is usually related to a low-order bending mode of, for example, the tool holder shank in external turning, the boring bar in internal turning, and spindle-cutter assembly in milling.^{10,11,13,16,17} Frequently, the tool holder responses during continuous unstable machining have nonlinear properties.^{10,11,13,14,18} Boring bar vibration, for instance, usually has spectra containing harmonics of the dominating resonance frequency as well

Figure 3 Structure of (a) SS 0727-02 or AISI 80-55-06 (magnification 1000 \times). (b) SS 2343-02 or AISI 316 (magnification 50 \times).¹³

as non-Gaussian probability density.^{10,11} Occasionally, these properties may also be observed in tool holder shank vibration in external turning which, however, usually is Gaussian distributed.^{13,18} For constant cutting data, tool holder shank vibrations in external turning are generally described well by second-order weakly stationary random processes, while boring bar vibrations usually exhibit nonstationary stochastic behavior.^{10,11,13} Low-frequency revolution-dependent workpiece motion due to residual rotor mass unbalance in the spindle–chuck–workpiece system may influence the motion of the tool holder via the relative dynamic motion between the cutting tool and workpiece. As a result, the motion of a tool holder is influenced by force modulation¹⁰ and thus exhibits cyclostationary properties.¹⁹ In milling, both the tooth pass frequency and the residual rotor mass unbalance in the spindle–cutter assembly may also influence the tool holder response during machining.^{14,16,17}

3 METHODS OF VIBRATION AND CHATTER CONTROL
